KEYWORDS. DNA origami, gold nanoparticles, metallization, electrical contacting, charge
transport

ABSTRACT. DNA origami nanostructures have been used extensively as scaffolds for
numerous applications such as for organizing both organic and inorganic nanomaterials, studying
single molecule reactions and fabricating photonic devices. Yet, little has been done towards the
integration of DNA origami nanostructures into nanoelectronic devices. Among other challenges,

1
2
3 the technical difficulties in producing well-defined electrical contacts between macroscopic
4 electrodes and individual DNA origami-based nanodevices represents a serious bottleneck that
5
6 hinders the thorough characterization of such devices. Therefore, in this work, we have
7
8 developed a method to electrically contact individual DNA origami-based metallic nanowires
9
10 using electron beam lithography. We then characterize the charge transport of such nanowires in
11
12 the temperature range from room temperature down to 4.2 K. The room temperature charge
13
14 transport measurements exhibit ohmic behavior, whereas at lower temperatures, multiple charge
15
16 transport mechanisms such as tunneling and thermally assisted transport start to dominate. Our
17
18 results confirm that charge transport along metallized DNA origami nanostructures may deviate
19
20 from pure metallic behavior due to several factors including partial metallization, seed
21
22 inhomogeneities, impurities, and weak electronic coupling among AuNPs. Besides, this study
23
24 further elucidates the importance of variable temperature measurements for determining the
25
26 dominant charge transport mechanisms for conductive nanostructures made by self-assembly
27
28 approaches.

39 INTRODUCTION

40 One-dimensional (1D) nanostructures, such as nanotubes, nanorods and nanowires have
41
42 received broad interest due to the unique properties associated with their nanoscale dimensions
43
44 and their potential for integration with semiconductor devices.^{1,2} Particularly, metallic nanowires
45
46 have attracted a great deal of attention as they can be used as interconnects in fabricating
47
48 nanoelectronic devices³ and for chemical and biological sensing applications,⁴ mainly due to
49
50 their high surface-to-volume ratio and their fundamental electronic and optoelectronic properties
51
52 as a result of quantum confinement effects.⁵ In the past, various routes for the fabrication of 1D
53
54 nanostructures have been demonstrated.^{6,7} Among other methods, molecular self-assembly⁷ has
55
56
57
58
59
60

1
2
3 shown great promise for the synthesis of both organic and inorganic nanostructures. Particularly,
4 DNA-based self-assembly⁸ is currently considered a powerful and versatile method for
5 constructing nanostructures with varying degrees of complexity. For instance, the DNA origami
6 technique⁹ introduced by Rothemund in 2006 has proven its capabilities as a reliable method for
7 synthesizing well-defined organic nanostructures by folding a long single-stranded DNA scaffold
8 with the help of short synthetic staple strands. By this method, quasi 1D DNA nanostructures
9 have been demonstrated¹⁰, and these DNA origami nanostructures have been further used as
10 scaffolds for the precise positioning of metallic nanoparticles^{11–17} with few nanometer resolution
11 and for the fabrication of linear and branched metallic nanowires.^{18–21} With the development of
12 the DNA origami technique⁹ the fabrication of complex DNA-based metallic nanostructures
13 became possible since it allows for the synthesis of DNA origami templates of arbitrary
14 shape,^{9,22–25} as well as a selective metallization by decoration of selected regions of the DNA
15 origami surface with DNA-modified nanoparticle seeds via hybridization to protruding staple
16 strands.^{19,21} Hence, metallization of various DNA origami shapes has been demonstrated.^{18–21,26–}

41 Although the metallization of DNA origami has been extensively studied, there are only few
42 reports so far that show electrical measurements of the charge transport through the metallized
43 DNA origami nanostructures.^{19,21} In part, this is due to the technical difficulties in producing
44 well-defined electrical contacts between macroscopic electrodes and individual DNA origami-
45 based nanowires. Previously, electrical contacting was achieved by random deposition of the
46 metallized DNA origami from solution onto arrays of inter digital electrode arrays with small
47 gaps. The smaller the gap between the electrodes, the higher the probability that a metallized

40 Therefore, in this work, we demonstrate the precise electrical contacting of individual
41 metallized DNA origami nanowires and characterize their charge transport behavior at different
42 bias voltages and temperatures. The schematic representation in figure 1 summarizes our
43 experimental strategy. We first decorate DNA origami nanotubes with 14 AuNPs along the
44 nanotube axis. Then, commercially available gold plating solution is applied to selectively grow
45 the gold nanoparticles until they fuse with each other and create eventually continuous
46 nanowires. Finally, we develop a method to electrically contact individual nanowires and
47 characterize their charge transport behavior by I-V measurements at different temperatures.

10 11 12 **EXPERIMENTAL**

13
14 The six-helix bundle DNA origami nanotube originally designed by Bui et al¹⁰ was adopted as
15
16 metallization template in this work. As previously reported,²⁹ the DNA origami assembly was
17
18 performed by mixing the M13mp18 viral DNA scaffold (New England Biolabs) with the 170
19
20 staple strands (Metabion) in a 1:30 molar ratio in TAE buffer containing 20 mM Mg²⁺ (Sigma-
21
22 Aldrich) in a total volume of 100 μ L. For the attachment of AuNPs, 28 staple strands (Metabion)
23
24 out of 170 total strands were modified on their 5' end with a protruding 5'-(AAT)₈T₄-3'
25
26 sequence, and citrate-stabilized 5 nm AuNPs (BBI) were coated with a complementary sequence
27
28 5'-(ATT)₃T₄-3' as described previously.¹¹
29
30
31
32
33
34

35 AuNP assembly on DNA origami nanotubes was performed at room temperature on 500 nm
36
37 SiO₂ thermally grown on Si substrates. First, the SiO₂ substrate was cleaned in an oxygen plasma
38
39 for 3 min and rinsed with ethanol and water. After drying the substrate in a stream of N₂, DNA
40
41 origami solution (concentration ~1 nM) was deposited on the surface and incubated for 1 h in
42
43 10xTAE/200 mM Mg²⁺ in a humidity chamber. After incubation, the substrate was dipped in a
44
45 1:1 mixture of ethanol and Milli-Q water for 30 seconds to remove residual salt from the surface
46
47 and dehydrate the DNA origami. After drying in a N₂ stream, hybridization of AuNPs with the
48
49 immobilized DNA origami nanotubes was performed by depositing the DNA-coated AuNPs
50
51 solution (concentration 50 nM) on the substrate surface and incubating further for 10 min at
52
53 room temperature in 1 \times TAE buffer containing 50 mM MgCl₂ as previously reported.¹¹ The
54
55
56
57
58
59
60

1
2
3 excess DNA-coated AuNPs and the residual salt were then removed by dipping the substrate first
4 in Milli-Q water for 10 seconds and then in a 1:1 mixture of ethanol and Milli-Q water for 30
5
6 seconds. The concentration of the DNA-coated AuNPs solution was estimated by UV/vis
7
8 spectroscopy from the optical absorbance at 520 nm. Imaging and characterization of AuNP
9
10 modified DNA origami was performed by tapping mode atomic force microscopy (AFM) in air
11
12 using a Bruker MultiMode 8 scanning probe microscope and PPP-NCLR cantilevers from
13
14 Nanosensors (nominal force constant 48 N m⁻¹, tip radius <10 nm).
15
16
17
18
19
20
21

22 For the metallization of AuNP modified DNA origami nanotubes, commercially available Au
23
24 plating solution (GoldEnhance EM, Nanoprobes) was used. First, a 1:1 mixture of Au plating
25
26 solution and 1x TAE buffer containing 10 mM Mg²⁺ was prepared. Then, the final solution was
27
28 dropped immediately on the AuNP modified DNA origami surface and incubated for 10-20 min.
29
30 The substrate was then dipped in Milli-Q water for 10 s and dried in a N₂ stream. Metallized
31
32 DNA origami nanotubes were imaged by AFM and scanning electron microscopy (SEM). All the
33
34 topographic AFM were analyzed using Gwyddion open source software.³⁰
35
36
37
38
39
40

41 After the metallization process, the electrodes and the connection pads were fabricated using
42
43 electron beam lithography (Raith eLINE Plus). First, ZEP (commercially available e-beam resist
44
45 - Zeon) electron beam resist was spin coated on top of the substrate and baked at 150°C for 10
46
47 minutes. Then, the resist was exposed to an electron beam at 10 kV acceleration voltage. After
48
49 electron exposure, the resist was developed by immersing the substrate first in N-amyl acetate
50
51 for 90 seconds and then in isopropanol (IPA) for 30 seconds. A buffer layer of 5 nm Ti was then
52
53 deposited on the sample by electron beam evaporation at a rate of 1 Å/s, followed by 50 nm Au
54
55
56
57
58
59
60

1
2
3 at a rate of 2.2 Å/s (working pressure $\sim 10^{-9}$ mbar). After Au deposition, lift-off of resist was
4
5 performed by submerging the substrate in acetone for 10 minutes and subsequent washing with
6
7 IPA followed by drying in a stream of N₂.
8
9

10
11
12 All electrical measurements were carried out in vacuum ($\sim 10^{-5}$ mbar) in the dark using a
13
14 Keithley 2400 source meter. For temperature dependent electrical characterization, a helium gas-
15
16 flow cryostat system was used. To observe the effect of temperature on charge transport, samples
17
18 were first cooled down to 4.2 K, and measurements were obtained when the samples were
19
20 subsequently heated up to room temperature. All current measurements were obtained by
21
22 sweeping the voltage range from -1V to +1V.
23

29 **RESULTS AND DISCUSSION**

30 For this work, quasi 1D DNA origami nanotubes with a nominal length of 412 nm and a
31
32 nominal diameter of 6 nm were used. As previously reported,¹¹ the DNA origami nanotube was
33
34 first modified to create 14 binding sites that can be used for the attachment of 14 AuNPs along
35
36 the nanotube axis. Each binding site has two sticky ends protruding from two neighboring
37
38 helices, and in total 28 staple strands were elongated by adding a capturing sequence on their 5'
39
40 end (Figure 1). Figure 2a shows an AFM image with corresponding line scan (Figure 2a, inset)
41
42 of the adsorbed and dried DNA origami nanotubes. The mean height of the nanotubes (Figure 2a,
43
44 inset) is reduced by almost 3.5 nm due to dehydration and interaction with the surface.

Figure 2. AFM height images with corresponding line scans (inset) for bare DNA origami nanotubes (a), AuNP-modified (b) and metallized (c) DNA origami nanotubes. All the topographic AFM images have 15 nm height scale. Insets have scale bars of 100 nm length.

For AuNPs attachment, we used our previously optimized protocol¹¹ to achieve a high nanoparticle assembly yield with few unbound background particles. Figure 2b shows an AFM image of AuNP-decorated DNA origami. An attachment yield > 96% was obtained, providing a high and uniform seed density which is essential for further metallization.

In order to optimize the metallization of the DNA origami nanotubes, various incubation times have been tested (see electronic supporting information). Figure 2c shows an AFM image of the metallized DNA origami nanotubes after 20 minutes of incubation time. The inset in figure 2c confirms that the 5 nm AuNP have grown to ~ 30 nm diameter. For better visualization, the sample was further characterized by SEM (Figure 3). The metallized DNA origami nanostructures are well-defined and appear continuous.

Figure 3. SEM image of metallized DNA origami nanotubes. The zoomed image shows the well-defined structure of the nanowires.

In order to electrically contact individual nanowires, we have developed an optimized method using electron beam lithography. First, parallel arrays of gold alignment marks (gap $\sim 25 \mu\text{m}$) were patterned using standard procedure on top of the SiO_2 substrate with pre-deposited DNA origami. Then, several SEM images were taken to determine a suitable nanowire density, corresponding to approximately one nanowire per $1 \mu\text{m}^2$, and to register the x-y coordinates of the selected nanowires with respect to the alignment marks. After that, e-beam resist was deposited for defining contacts to selected nanowires. The registered location of the nanowires were then used to obtain the correct e-beam exposure position. In this way, electrical contacts to the individual nanowires were fabricated with high accuracy (Figure 4). Interestingly, the metallized DNA origami nanostructures strongly adhere to the substrate and sustain their shape during the lithography process. For the transport measurements, we contacted two nanowires with different morphologies. The first nanowire (NW-1, Figure 4a) consists of closely packed AuNPs, and due to random nanoparticle aggregation, the width of the nanowire seems greater than the actual single nanowire (between 30 and 75 nm). The second nanowire (NW-2, Figure

1
2
3 4b), on the other hand, features only the AuNPs attached to the single DNA origami nanotube
4 and thus has a smaller effective width around 30 nm. The zoomed image in Figure 4b shows,
5 however, that there may be small gaps (~ 1 to 3 nm) between neighboring AuNPs. A closer
6 inspection of the grown AuNPs in the zoom shown in figure 4b reveals that some of the AuNPs
7 preferentially grown in a lateral direction, leaving very small gaps between neighboring AuNPs.
8 Although it is unclear at the moment why the AuNPs show this lateral growth, we speculate that
9 it results from hindered diffusion of gold ions in the narrow gaps between the particles i.e. the
10 ions' diffusion is becoming less and less efficient with increasing particle size. Note that under
11 our experimental conditions, both increasing the Au plating time and repeating the plating
12 process did not solve this issue but only led to stronger particle aggregation and larger nanowire
13 widths.

60

Two-terminal current-voltage measurements were performed on both nanowires in the temperature range between room temperature and 4.2 K and in the voltage range between -1 V and $+1$ V at $\sim 10^{-5}$ mbar in the dark. The I-V curves in the insets of Figure 5a,b reveal that the two metallized nanowires exhibit ohmic behavior at room temperature with the measured current of NW-1 (Figure 5a, inset) being about 30 times larger than for NW-2 (Figure 5b, inset). This observation is consistent with the different morphologies of the nanowires as observed in Figure 4a,b and agrees with previously reported measurements^{19,21} on metallized DNA origami nanostructures performed at room temperature. However, the measured resistance values of NW-1 (~ 116 M Ω) and NW-2 (~ 2.8 G Ω) are much higher than previously reported values of comparable nanowires (\sim K Ω).¹⁹ In addition, the variable-temperature measurements (4.2 K to 300 K) performed on both nanowires show that the electrical conductance of the nanowires decreases with temperature (Figure 5), contradicting purely metallic behavior.

1
2
3 **Figure 5.** Temperature-dependent I-V characteristics for NW-1 (a) and NW-2 (b) over the
4 temperature range from 4K to 300K. Insets are room-temperature I-V curves. All transport
5 measurements were carried out under high vacuum in the dark.
6
7
8
9

10
11
12
13
14 To rationalize the electrical conductance of the nanowires, we consider several possible
15 conduction mechanisms. Since the charge transport measurements show a decrease of
16 conductance as a function of temperature, we first discuss temperature-dependent models such as
17 hopping and thermionic emission conduction. In the hopping conduction model,³¹⁻³³ thermally
18 activated electrons escape from one trap to another due to thermal fluctuations, and the
19 conductance can be expressed in terms of temperature using,
20
21
22
23
24
25
26
27

$$28 \quad G \sim \exp\left(-\frac{E_a}{kT}\right), \quad (1)$$

29
30
31
32 where G is the conductance, E_a the activation energy, k Boltzmann's constant and T the
33 temperature. By plotting the natural logarithm of the conductance as a function of inverse
34 temperature ($\ln(G)$ vs $1/T$), we determine the thermally activated transport regime. Figure 6a
35 displays the plot $\ln(G/G(300K))$ vs. $1/T$ for NW-1 and NW-2 at 1V positive bias voltage over the
36 temperature range from 4.2 K to 300 K. Both nanowires show that at low temperatures, the
37 conductance exhibits no significant temperature dependence, whereas at intermediate and high
38 temperatures, thermally activated transport is observed. The respective activation energy³² of
39 each nanowire can be extracted from the slope of $\ln(G/G(300K))$ vs $1/T$ in figure 6b, which yields
40 24.1 meV for NW-1 and 72.5 meV for NW-2. The difference between the activation energy
41 values of the two nanowires stems from their different morphologies and sizes. As seen in figure
42 4, NW-1 shows a much denser agglomeration of particles than NW-2. As a consequence, the
43
44
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 nanoparticles in NW-1 are forming a nanowire which has approximately twice the width of NW-
4
5
6 2. This explains the lower energy of this wire compared to the thinner wire: The number of
7
8 interconnects is increased by more than a factor of 2, and thus the transport energy is decreased
9
10 by a similar factor. However, this linear fit holds only in the high temperature region from 100 K
11
12 to 300 K for NW-1 and from 200 K to 300 K for NW-2, suggesting that hopping conduction
13
14 dominates at higher temperatures.³² We have also observed similar fits for different bias voltages
15
16 which in turn supports the hopping conduction model. Hopping has been previously observed in
17
18 metal contacts to self-assembled molecular monolayers with rather similar activation energies³⁴.
19
20 In such junctions, it could be shown that the activation energy depends on the nature and the
21
22 surface morphology of the contacting metal³⁵. Hence, the granularity of the metal leads to
23
24 Coulomb blockade at low temperatures. In the DNA origami-based nanowires characterized in
25
26 this work, however, the grain sizes are larger than in evaporated films; therefore Coulomb
27
28 blockade effects are not observed. Besides, previous studies³⁶ on the conductivity along partially
29
30 metallized λ -DNA also concluded that the transport at high temperature is dominated by hopping
31
32 conduction. It is, however, presently unclear whether the thermally activated electrons hop along
33
34 residual non-metallized DNA structures between grown AuNPs or through impurities.

Figure 6. (a) Normalized natural logarithm of the conductance vs $1/T$ for NW-1 and NW-2 and (b) the respective linear fits to the data for certain temperature ranges. (c) Plots of $\ln(I/T^2)$ vs $1/T$ for NW-1 and NW-2 and (d) the respective linear fits to the data points for certain temperature ranges. The fits in (b) and (d) reveal that thermally assisted transport is dominating in NW-1 at lower temperature than in NW-2. The voltage bias is 1 V.

1
2
3 Similarly, the thermionic emission model in which electrons are thermally excited over the
4 barrier instead of tunneling directly through the potential barrier is also examined. The
5 temperature dependence of the current is given by,³⁷
6
7
8
9

$$I \sim T^2 \exp\left(\frac{\phi - q\sqrt{qV/4\pi\epsilon d}}{kT}\right) \quad (2)$$

10
11
12 where, I is the current, T the temperature, ϕ the barrier height, V the bias, ϵ the dielectric
13 constant, k Boltzmann's constant, d the barrier width, and q the electron charge. Figure 6c shows
14 the plot of $\ln(I/T^2)$ vs $1/T$ for 1 V bias voltage for NW-1 and NW-2 over the temperature range
15 from 4.2 K to 300 K. The linear fits in figure 6d demonstrate that similar to hopping conduction
16 at high temperatures, thermionic emission is observed at lower temperatures between 25 K and
17 100 K for NW-1 and between 50 K and 200 K for NW-2. However, no thermally assisted
18 transport is observed < 25 K for NW-1 and < 50 K for NW-2 (Figure 6a). Since the measured
19 conductance at low temperature regimes is independent of temperature and follows a linear
20 voltage dependence, the conduction mechanism can essentially be characterized by direct
21 tunneling.³⁸ Although, direct tunneling is an important mechanism of transport in the self-
22 assembled nanowires, it is difficult to extract the necessary parameters such as the barrier height
23 from the tunneling current. It requires accurate measurements of the gap between the
24 nanoparticles, which is not well-controlled under our experimental condition. Therefore, we
25 conclude that different transport mechanisms are contributing to the overall transport in different
26 temperature ranges. At low temperatures, the transport is dominated mainly by tunneling through
27 the barrier, and as temperature increases the barrier decreases slightly, allowing more electrons
28 to be excited over the barrier through a thermionic process. At high temperatures, hopping
29 conduction governs the transport.

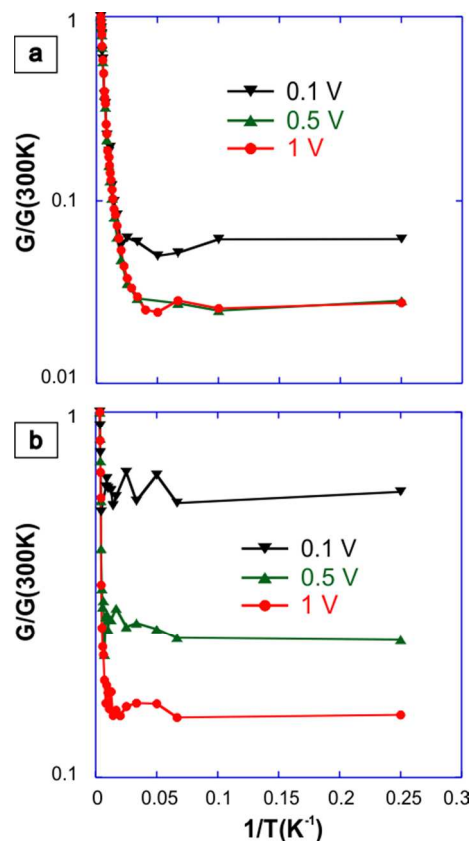

Figure 7. The natural logarithm of the normalized conductance vs $1/T$ for NW-1 (a) and NW-2 (b) for different biases.

We have also investigated the bias voltage dependence of the transport. Figure 7 depicts the conductance as a function of temperature for NW-1 (Figure 7a) and NW-2 (Figure 7b) at different forward bias voltages. In NW-2 (Figure 7b), no significant temperature dependence of the conductance is observed at low bias voltages (< 0.1 V), whereas in NW-1 (Figure 7a), thermally activated transport is found even at low bias voltages. We attribute this to the fact that the measured current at low bias voltage in NW-2 was too noisy to extract temperature dependent transport properly. Besides, at low bias voltage (0.1 V), a lower temperature dependency is observed in NW-2 compared to NW-1 (Figure 7), and as the voltage further increases (0.5 V), the effect of electric field becomes insignificant for NW-1. These observations

1
2
3 can again be explained by the different morphologies of the nanowires with NW-1 providing
4 more paths than NW-2 for electrons to flow to the electrodes. Apart from this, the measured data
5 exhibit no Fowler-Nordheim tunneling transport behavior. Therefore, we argue that the variable-
6 temperature measurements not only elucidate the fact that the two nanowires reflect similar
7 transport mechanisms despite their structural differences but also confirm that charge transport
8 along metallized DNA origami nanostructures may deviate from pure metallic behavior due to
9 several factors including partial metallization, seed inhomogeneities, impurities, and weak
10 electronic coupling among AuNPs.

24 CONCLUSIONS

25 In summary, we have fabricated DNA origami-templated nanowires by metallization of DNA
26 origami nanotubes and electrically contacted individual nanowires using electron beam
27 lithography. We measured the electrical conductance of the metallized nanowires at various
28 temperatures from room temperature down to liquid helium temperature for two different
29 nanowire morphologies. At room-temperature, the I-V curves for both nanowires showed linear
30 behavior, in agreement with previous reports. However, the temperature-dependent
31 measurements indicate that multiple transport mechanisms contribute to the overall conductance
32 of the nanowires in different temperature regimes. At low temperature, tunneling dominates the
33 transport, whereas at intermediate and high temperatures, thermionic and hopping conduction
34 governs the charge transport, respectively. Although the metallized DNA origami nanotubes
35 deviate from pure metallic behavior, further tuning of the transport behavior is possible either by
36 improving the metallization process or adding conductive molecules between the grown AuNPs
37 which can be used for developing novel electronic devices displaying new functionalities.^{39,40}
