Abstract

40 kV high-resolution transmission electron microscopy (TEM) experiments are performed to understand defect formation and evolution of their atomic structure in single-layer 2H MoTe₂ under electron beam irradiation. We show that Te vacancies can agglomerate either in single Te-vacancy lines or in extended defects composed of column Te vacancies, including rotational trefoil-like defects, with some of them being never reported before. The formation of inversion domains with mirror twin boundaries of different types, along with the islands of the metallic T' phase was also observed. Our first-principles calculations provide insights into the energetics of the transformations as well as the electronic structure of the system with defects and point out that some of the observed defects have localized magnetic moments. Our results indicate that various nano-scale structures, including metallic quantum dots consisting of T'-phase islands and one-dimensional metallic quantum systems such as vacancy lines and mirror twin boundaries embedded into a semiconducting host material can be realized in single-layer 2H MoTe₂, and defect-associated magnetism can also be added, which may allow prospective control of optical and electronic properties of two-dimensional materials.

Introduction

Transition metal dichalcogenides (TMDs) with a general structural formula MX₂, where M stands for a transition metal (*e.g.*, Mo, W, Re) and X for chalcogen atoms (S, Se, Te) are layered materials, which can, depending on the constituent chemical elements, be insulators, semiconductors, metals, superconductors or charge density waves insulators.¹⁻⁴ Single structural units (sheets) of TMDs can be produced by exfoliation¹ or grown by chemical vapor deposition,⁵ and these two-

dimensional (2D) systems have been shown⁵⁻⁸ to possess many interesting properties with numerous implications for potential applications such as atomic defect based quantum emitters.^{9,10} Moreover, even for the same chemical composition, these compounds exist in several crystalline phases with drastically different properties.^{3,6-8} For example, the hexagonal 2H phase in Mo-containing TMDs is normally semiconducting, while the metastable monoclinic (1T') phase is metallic.

Among TMDs, MoTe₂ is one of the most interesting materials, as the energy difference between its 2H and 1T' phases is very small (~31 meV per formula unit),¹¹ and the transformation from the 2H to 1T phase can be rather easily induced by electrostatic doping¹² or laser processing.¹³ The precise control of the atomic structure offers opportunities for engineering the electronic properties,¹⁴ device fabrication¹³ and catalysis.¹⁵ Moreover, the properties of MoTe₂ can further be tuned by a controllable introduction of defects. Vacancies were shown¹³ to facilitate a transition from the H to T phase, and be efficient catalytic centers.^{15,16} Metal vacancies and chalcogen-metal antisites were demonstrated to promote magnetism, adding thus functionalities to this system.¹⁷

Agglomeration of defects, either vacancies or Mo interstitials, can give rise to the formation of inversion domains and associated mirror twin boundaries (MTBs),^{14,18,19} which can exhibit very peculiar behavior,²⁰ as one-dimensional metallic quantum objects confined into a semiconducting matrix. Inversion domains with MTBs can be formed in 2D TMDs under electron irradiation in a transmission electron microscope (TEM) utilizing the electron beam both as an imaging tool and a means to functionalize the material,^{19,21,22} or by depositing extra Mo atoms at elevated temperatures.²³ As compared to other TMDs, the formation of a dense network of inversion domains is particularly easy in MoTe₂ due to its larger unit cell size as compared to other Mo-based TMDs, which makes the interstitial site more accessible for extra atoms.²³

However, in spite of a few theoretical and experimental works on MoTe_2 ^{24–26} and other TMDs,^{22,26–33} neither the mechanism of the formation of these defects nor their evolution under the electron beam is fully understood. The atomic structure¹⁴ of the emerging MTBs appear to depend on the material and experimental conditions, and electron irradiation sometimes gives rise to the development of vacancy lines, but not MTBs.^{22,24,31,32} It is not clear what role point defects play in MTB formation, or how mechanical strain affects this process. The exact structure and directions (armchair, zigzag) of the line defects can be quite different,^{28,31} and the reason for this observation remains elusive, partly because contrast and resolution are limited in conventional spherical aberration-corrected TEMs.

Here, we use not only spherical (Cs), but also chromatic (Cc) aberration-corrected high-resolution (HR) TEM at an electron acceleration voltage of 40 kV, resulting in increased resolution and contrast,^{34–36} to get microscopic insights into defect appearance and evolution under electron beam in 2D MoTe_2 . We combine our Cc/Cs-corrected HRTEM experiments with first-principles calculations carried out within the framework of the density functional theory (DFT) to systematically study defect formation, migration and coalescence. We follow the transformations atom-by-atom and show that single tellurium vacancies agglomerate either in short vacancy lines, extended trefoil-like defects, and ultimately form inversion domains. Our theoretical data on magnetic and electronic properties of electron-beam modified MoTe_2 show that certain functionalities can be added to the system, such as quantum dots and quantum wires, through a controllable introduction of particular defects, which lead to application-related control of optical, electronic and magnetic properties of 2D TMDs.

Experimental Section

Sample preparation:

Molybdenum ditelluride monolayers were exfoliated via an adhesive tape, on silicon dioxide substrates with thickness of 90 nm as it is shown in figure 1, (i) and (ii). With an optical microscope, monolayers were identified due to contrast measurements and compared to calculations with the Fresnel formula,^{37,38} which yields to a contrast of ~ 46 % for a monolayer of MoTe₂ on 90 nm SiO₂ illuminated with green light. After a monolayer is located, a Quantifoil TEM grid R 1.2/1.3 is placed with a drop of isopropyl alcohol on top. Due to the evaporation of the isopropyl alcohol the grid comes into contact with the flake (iii). With a drop of potassium hydroxide (KOH) the SiO₂ is etched away and therefore releases the grid with the MoTe₂ flake (iv). Afterwards, the residues of the preparation are removed with double distilled water. Although some regions in the single-layer MoTe₂ are contaminated, there are still sufficient clean areas for the TEM investigations.

TEM conditions:

The high-resolution TEM images were acquired at the Cc/Cs – corrected Sub-Angström Low-Voltage Electron microscope (SALVE) at a voltage of 40 kV. Measured values for Cc and Cs were in the range of -10 μm to -20 μm . The vacuum in the column of the TEM was in the range of 10^{-5} Pa. Dose rates in the range of 10^6 e⁻/nm²s were used and the images were recorded on a 4k x 4k camera with exposure times of 1s.

Image simulations:

The image calculation has employed the following experimental parameters: A focal spread of 0.5 nm, an image spread of 30 pm, a convergence angle of 0.1 mrad and a sampling of 0.16 Å/pixel to account for the influence of the CCD camera. Furthermore, the 5th-order spherical aberration C5

was set to 1.8 mm and the following aberration coefficients were optimized and used for the image calculation: a defocus of 7.5 nm and 3rd-order spherical aberration coefficient Cs of - 8.2 μm .

Computational Methods:

The density functional theory calculations have been performed based on the generalized gradient approximation (GGA) with Perdew-Burke- Ernzerhof (PBE)³⁹ for exchange-correlation function as implemented in VASP code.⁴⁰ The atomic structures of MoTe₂ monolayers with various defects have been fully optimized using 10 \times 10 supercells. The maximum force during the optimization was set to be less than 0.01 eV/Å. A plane-wave basis set with an energy cutoff of 400 eV is used. The Brillouin zone of the supercells was sampled using 4 \times 4 \times 1 k-points for optimization according to the scheme proposed by Monkhorst and Pack.⁴¹ Formation energies of defects have been calculated as $E_f = E_{def} - (E_{pristine} - \mu_x)$, where E_{def} is the energy of the system containing defect and $E_{pristine}$ is the energies of the pristine system. μ_x stands for the chemical potential of the X species, which is taken as the spin-polarized energy of the isolated atom.

Results and Discussions

Figure 2 shows a 40 kV Cc/Cs-corrected high-resolution (HR)TEM image in bright atom contrast where differences between the contrast of a single missing Te atom (Te vacancy) and two missing Te atoms (Te divacancy-column) can be clearly seen as marked in (a) by the green and blue arrows, respectively. It should be noted that sub-Ångström resolution (0.9 Å) is achievable at 40 kV electron accelerating voltage, and our technique allows a fully atomic position-corrected image acquisition within a short timescale (\sim 1s) over a large field of view.³⁵ Any ballistic damage should be excluded at 40 kV due to high mass of Te and Mo atoms,⁴² the maximum transferrable kinetic

energy is 0.72 eV and 0.95 eV for the Te and Mo atoms, respectively. This is far below the formation energy for a Te vacancy (4.87 eV) and Mo vacancy (10.45 eV). We stress that the displacement thresholds are generally higher than the formation energies because a part of the deposited energy can be transferred to the atoms neighboring the recoil atom, which in addition to that may also need to overcome a potential barrier.⁴² However, the electron beam is responsible for vacancy production. Figure S1 in the Supporting Information (SI) shows the increasing vacancy concentration from ~ 0.17 vacancies/nm² to ~ 0.27 vacancies/nm² after a total accumulated dose of $\sim 1.2 \cdot 10^8$ e/nm². The exact mechanism of defect formation is not known, but it is likely beam-induced chemical etching⁴³ resulting from the reactive species, *e.g.*, fragments of water and other molecules present in the TEM column and thus on the sample surface, is responsible for the appearance of defects. Further damage accumulation likely proceeds through the localization of beam-induced electronic excitations on the existing defects resulting in the promotion of electrons into anti-bonding orbitals and bond-breaking.

As can be seen in Figure 2 (a), single Te vacancies and column Te divacancies occur frequently in the lattice due to the interaction with the electron beam as shown previously for other TMDs such as MoS₂, MoSe₂ and NbSe₂.^{28–30} The line scan region in Figure 2 (c), obtained from the dashed area in (b), indicates that one missing Te atom produces still a slightly higher signal than a neighboring Mo atom (the mass is 127.60 u for Te and 95.94 u for Mo), the green diagram in Figure 2 (c), and two missing Te atoms on top of each other (column divacancy) can be identified by the strongly reduced signal in the corresponding blue line-scan (see the framed area). The faint signal might result from neighboring Mo atoms, which slightly fall into with the line scan region. In addition, small contrast contribution is also a consequence of multiple scattering of the electron

wave within the atomic layers of single-layer MoTe₂. This effect can introduce weak contrast within the fully stoichiometric rings.⁴⁴

The appearance of point defects and the migration of Te atoms in MoTe₂ was observed earlier with STEM.²⁵ The authors reported also rotationally symmetric defects, as well as line defects such as mirror twin grain boundaries.²⁵ As we show below, the morphology of defects produced in TEM is somewhat different from those obtained in the STEM mode. However, the TEM mode allows fast image acquisition with a large field of view, thus the dynamics and transformations of point defects into rotational and extended defects can be studied in detail. Furthermore, bigger surrounding areas of the defects can be taken into account for understanding the electron-beam-induced evolution due to the large field of view, shown in figure S1 in the SI.

In Figures 2 (d) and (e), structural models determined by DFT calculations are shown for a single vacancy (d) and a column divacancy, where two Te atoms on top of each other are missing (e). The calculated formation energies for a single Te vacancy and column divacancy are 4.87 eV and 4.46 eV per Te atom (in total $E_f(\text{Te}_2) = 8.92$ eV). These values are slightly lower than previously reported as different chemical potentials (with an account for spin polarization) of isolated atoms were used in the calculations.⁴² Although it is energetically more favorable to have a column divacancy than two single vacancies, the system is not under equilibrium conditions, and besides, the defects may be preferentially produced on one side of the sheet only, which may explain why we see more single vacancies in our experiments. The formation energy of Mo vacancies was found to be $E_f = 10.45$ eV per Mo atom, which is much higher than for Te. This is in line with the observations that only Te vacancies and related defects were present in our samples.

As evident from Figures 3 (a) – (c), the formation of more complicated defects where several atoms are missing, was also observed. Within the red frames in the lower images, the atoms are marked

with different colors (turquoise for Mo and orange for Te₂), which allows an easier comparison to the schematics of the transformation process presented in Figure 3 (d). In figure S2 in the SI, image simulations of the of the more complicated defects are given. We call these structures “extended point defects”, as they are between truly point defects, like single vacancies, and extended structures, like linear agglomerations of vacancies, which can be of infinite length. The formation of such defects starts with two column Te divacancies. Due to the migration of two Te atoms, which move into the center of the structure, a symmetric defect is formed, which we name Tetravacancy I. As a guide for the eye, black dashed lines and arrows in Figure 3 (d) indicate the distortion and migration of the atoms, respectively. The faint and slightly blurred contrast of the Mo atoms surrounding the Te₂ atom column in the center which appears in fig. 3 (a) but not in fig. S2 (a) in the Si, might be caused by vibrating Mo atoms, indicates that the Tetravacancy I may be a metastable configuration. Indeed, a distortion takes place, and Tetravacancy I turns into the distorted and more stable Tetravacancy II configuration, Figure 3 (b). After further electron irradiation and additional Te₂ vacancy formation, the distorted Tetravacancy II transforms into a symmetric trefoil-like defect structure (Trefoil I), Figure 3 (c). Due to a bond rotation, other types of tetravacancy and trefoil defects can be formed such as Tetravacancy III, IV and Trefoil II. However, these structures are less favored due to the higher formation energy (see Figures S3 and S4 in the SI), which is in line with the experimental HRTEM observations.

In order to study the electronic and magnetic properties of various extended defects, the spin-polarized total density of states (DOS) was calculated and shown in Figure 4. The presence of defects significantly changes the electronic structure and introduces a large number of midgap states. The defect-associated midgap states are mostly localized around the defects and thus the defects act as scattering centers affecting the electronic transport properties.⁴⁵ Moreover, due to the shift between the spin-up and spin-down states in the Tetravacancy I and II configurations,

these localized states have a magnetic character (*cf.* Figure 4). While pristine MoTe₂ with the 4d² configuration of Mo atoms is a non-magnetic material,⁴⁶ our calculations showed a total magnetic moment of 4 μ_B and 2 μ_B for Tetravacancy I and II configurations, respectively. Due to the locally changed electronic properties of the defect structures, embedded into a semiconducting matrix, they can be regarded as quantum dots. Similar behavior was also found for the less stable Tetravacancy IV (Figure S5 in SI). It should be mentioned that a single Te vacancy exhibits negligible spin polarization. The spin density plot of Tetravacancy I shows that the magnetism is mainly localized on the three Mo atoms surrounding the central Te atom, with some smaller contribution from the next adjacent Mo atoms. In the case of trefoil defects, the number of midgap states reduces when bonds are rotated and the system is non-magnetic.

During subsequent TEM imaging, the interaction of the electron beam with the MoTe₂ specimen resulted also in line defect formation. Figure 5 shows an experimental 40 kV Cc/Cs-corrected HRTEM image of a single vacancy line, composed of four missing Te atoms (a) together with the calculated HRTEM image (b) based on relaxed atomic coordinates determined by DFT calculations. The best fit with the experiment was found when assuming a slight sample tilt of 4°, which could be caused by a non-perfect sample – alignment. The lower panels of (a) and (b) are identical images, but for better defect visualization, the atoms within the red dashed area of the upper image are again marked with different colors: solid, orange dots mark two stacked-up Te (Te₂) atoms, orange rings mark one Te atom and the blue solid dots mark Mo atoms, the single vacancy line is framed. The comparison of the atom positions between experimental and simulated images show qualitatively good agreement, with minor differences possibly originating from the mechanical strain present in the system and associated with the loss of atoms.

To understand line defect formations, DFT calculations were performed for different Te vacancy-line structures and the atomic configurations are displayed together with their formation energies

in Figure 6. Te vacancy lines are either oriented in the zigzag direction (*cf.* Figure 6 (a) - (c)) or along armchair direction (*cf.* Figure 6 (e) - (g)). In either of the directions the Te vacancy-line can have four possible structures – a single vacancy line, a column divacancy line, a staggered divacancy line, and finally there are three missing Te atoms perpendicular to the vacancy line direction (shown in Figure S6 in SI). The tendency toward clustering of isolated vacancies can be investigated *via* the energy gain upon forming extended defects from isolated vacancies as a function of missing Te atoms. The negative values indicate the energy release when vacancies agglomerate into lines. It has been found that the vacancies are more prone to cluster along the zigzag direction than armchair direction. In the zigzag direction, Figure 6 (d), the energy release is about 0.04 eV and 0.6 eV per Te atom for a single vacancy line and staggered divacancy line, respectively.

As compared to the zigzag direction (d), Te vacancy lines in the armchair direction (h) are energetically less favorable. The formation of the single Te vacancy line and the staggered Te divacancy line is endothermic and thus unlikely. Only the column Te divacancy line releases energy upon agglomeration of vacancies, as previously reported.²⁶ Overall, the formation of vacancy lines along the zigzag directions is energetically preferable compared to armchair direction.

The spin-polarized total density of states (DOS) was calculated for different line defects along the zigzag direction, shown in Figure 7. As can be seen, states appear which can be interpreted as band gap reduction as compared to the pristine structure of MoTe₂, providing that the concentration of vacancy lines is high. A similar effect on the band gap has been observed for vacancy lines along the armchair direction (Figure S7 in SI). However, line defects can be regarded as quantum wires because of confined metallic properties within the semiconducting MoTe₂. Spatial localization of

spin up and down electron density indicates that some of these metallic structures, *e.g.*, column Te divacancy line could be used in spintronics.

As evident from Figure 6, the most favorable configuration is staggered Te divacancy lines followed by single Te vacancy lines both in zigzag direction. In the experimental images, we found only zigzag single Te vacancy lines, although point defects of column Te divacancies were often observed, Figure 2, while column or staggered Te divacancy lines were not present.

This observation and structural evolution of the defects under the electron beam can be understood in terms of the energetics of defects of various types. Figure 8 summarizes the formation energies for all defect structures including single vacancy lines, tetravacancies and trefoil-like structures. In the case of the single Te vacancies, the formation of lines is energetically favored. In the case of column Te divacancies their agglomeration to lines is only slightly preferred. However, their agglomeration to extended point defects releases a substantial amount of energy, as schematically indicated by the dashed path in Figure 8. Based on the energetics, one can expect that two column Te divacancies directly form the Tetravacancy II structure. Although, as described above, the Tetravacancy II structure can only be reached *via* the Tetravacancy I structure, which is metastable, so that the system prefers forming extended point defects, not column vacancy lines.

The formation of the Trefoil defect is due to further clustering of column Te divacancies. It has a formation energy of 3.88 eV per Te atom, so that it is strongly preferred over the Te divacancy line with the same number of missing atoms.

At higher vacancy concentrations, formation of inversion domains, Figure 9 (a)-(c), and local phase transformations from 2H to 1T' MoTe₂ phase, Figure 9 (d) – (f), occurred. In the case of the inversion domains, the observed MTBs evolve due to Te deficiency and form 4|4P and 4|4E boundaries as shown in Figure 9 (b). The shown inversion domain appeared due to electron beam

irradiation after a total accumulated dose of $\sim 1.4 \cdot 10^9 \text{ e}^-/\text{nm}^2$. Formation of 4|4P MTBs due to thermal annealing which leads to Te deficiency, similar to our electron-beam irradiation, were earlier reported.²⁴ However, the 4|4E MTB (*cf.* fig. 9(b)), based on Te deficiency was not observed earlier in MoTe₂. Panel (c) presents the same image as in panels (a) and (b) but, for better visualization the atoms are colored: solid orange dots mark two stacked-up tellurium (Te₂) atoms and the blue solid dots mark Mo atoms. The red arrows in (a) and (c) indicate the corners of the inversion domain.

Figure 9 (d) shows a single Te vacancy line with six missing Te atoms. The vacancy line is located between the red arrows. The displacements of Te atoms, indicated by white arrows, led to a formation of an island of 1T' phase in (e). Furthermore, the single vacancy line moved along a distance of two unit cells. A white dashed trapezoid is fixed in (d) and (e) at the same position to clarify the change in the structure. Figure 9 (d) and (e) are consecutive images with exposure times of 1s. Again, for better visualization, the atoms are colored in (f) like in (c) but this time also with the orange ring which marks a single Te atom. Similar transformations have been observed under electron beam in Re-doped MoS₂.³ The transformation likely originates from strain induced by vacancies and possibly other effects related to charge transfer and vibrational properties.^{11,25,47}

Conclusions

Our Cc/Cs-corrected HRTEM experiments performed at an electron acceleration voltage of 40 kV revealed a plethora of point and line defects in the HRTEM images of monolayer MoTe₂, and together with first-principles simulations, provided insights into their formation and evolution process. We demonstrated that Te vacancies can agglomerate either in single Te-vacancy lines or in extended defects composed of column Te vacancies, including rotational trefoil-like defects. Some of them, *e.g.*, Tetravacancy I and II have never been observed before. We also showed that

the formation of inversion domains with mirror twin boundaries of different types, along with the islands of the metallic T' phase can occur under the 40kV electron beam. Our first-principles calculations provided insights into the energetics of the transformations as well as the electronic structure of the system with defects. Specifically, we point out that some of the observed defects have localized magnetic moments, which may add functionalities to 2D MoTe₂ through defect engineering. Our results indicate that various nano-scale morphologies, including metallic islands of the T'-phase, and one-dimensional metallic systems based on vacancy lines and mirror twin boundaries embedded into a semiconducting host material can be realized in single-layer 2H MoTe₂. The former system can be referred to as a quantum dot, while the latter structure is very interesting in the context of fundamental aspects of the physics of Tomonaga-Luttinger liquid⁴⁸ and, as for practical aspects, plasmonics. Our calculations indicate that defect-associated magnetism can also be added to the system, which may lead towards control of optical and electronic properties for quantum devices in 2D materials.

Figures

Figure 1: Fabrication process of a freestanding MoTe₂ monolayer via exfoliation for TEM investigations

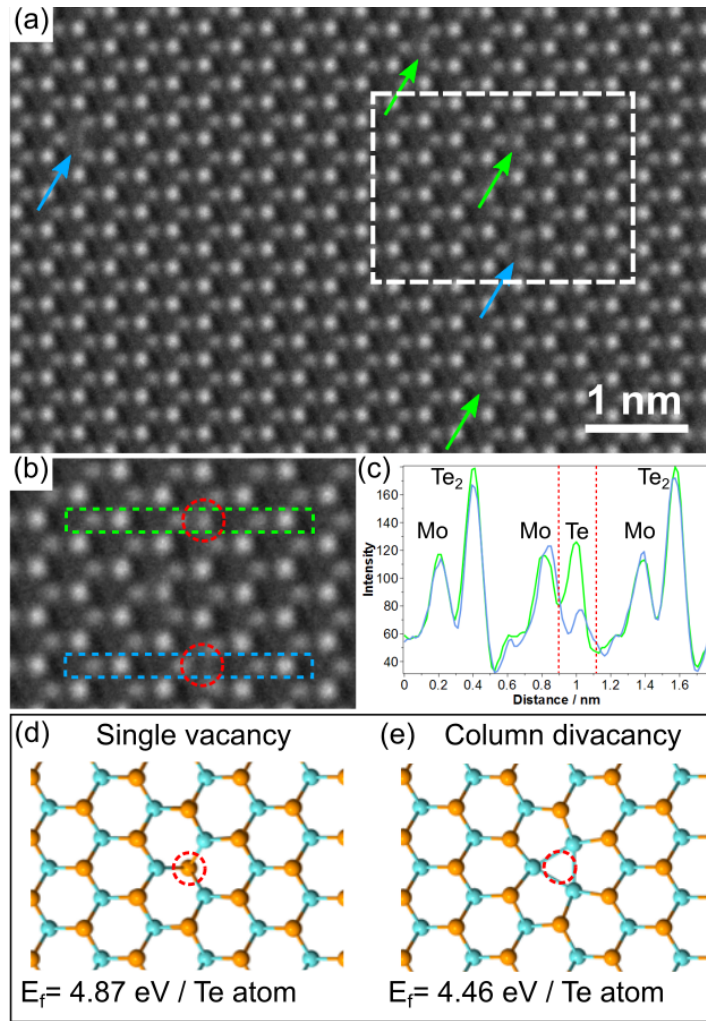

Figure 2: 40 kV raw data of Cc/Cs-corrected high-resolution TEM images of MoTe₂ is shown in (a) with different defects in bright atom contrast. A column of two Te atoms is brighter than one Mo atom. Single Te vacancies are marked with green arrows and column Te divacancies with blue ones. In the case of one missing Te atom, the contrast between the remaining Te is comparable to the contrast of the neighboring Mo atoms, which can be seen in the green line scan in (b). For column Te divacancies, the contrast vanishes as seen from the blue line-scan (c). Panel (d) shows a DFT-optimized structure of a single Te vacancy with the corresponding formation energy. The red dashed circles mark the position of missing Te atoms. Image (e) is the structure simulation of a column Te divacancy. Turquoise balls stand for Mo and orange ones for Te atoms.

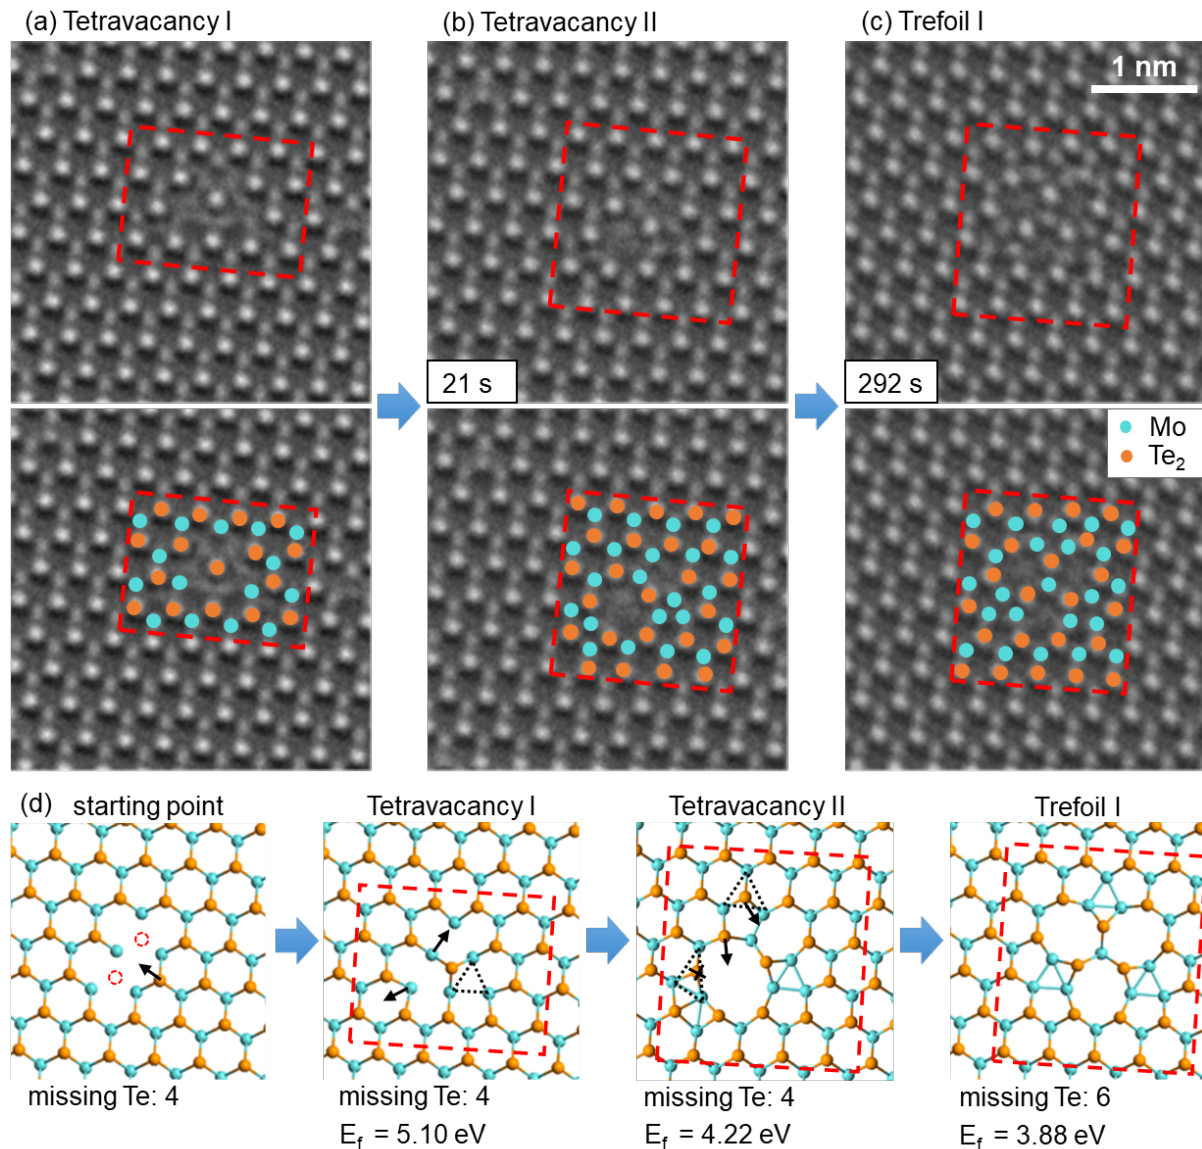

Figure 3: 40 kV Cc/Cs-corrected HRTEM images of 2-dimensional extended defects in MoTe₂ imaged in bright atom contrast. (a) shows the symmetrical Tetravacancy I structure, (b) a distorted Tetravacancy II structure which is formed after 21 s and (c) the trefoil-like structure (Trefoil I) after an additional 271 s. The dose rate was about $1.75 \cdot 10^6$ e⁻/nm²s. Images below are identical, however in the red-framed area atoms are marked: Mo atoms are turquoise and two Te atoms above each other are marked orange. The schematic representations in (d) show the corresponding structure simulations. Furthermore, the process of the experimental clustering of column divacancy

is presented. Due to tellurium migration, the intermediate Tetravacancy I forms from 2 column divacancies. Afterwards, the Tetravacancy I transforms into the stable Tetravacancy II structure and by forming further column Te divacancy, trefoil-like defect structures evolve (the given formation energies E_f are per Te atom).

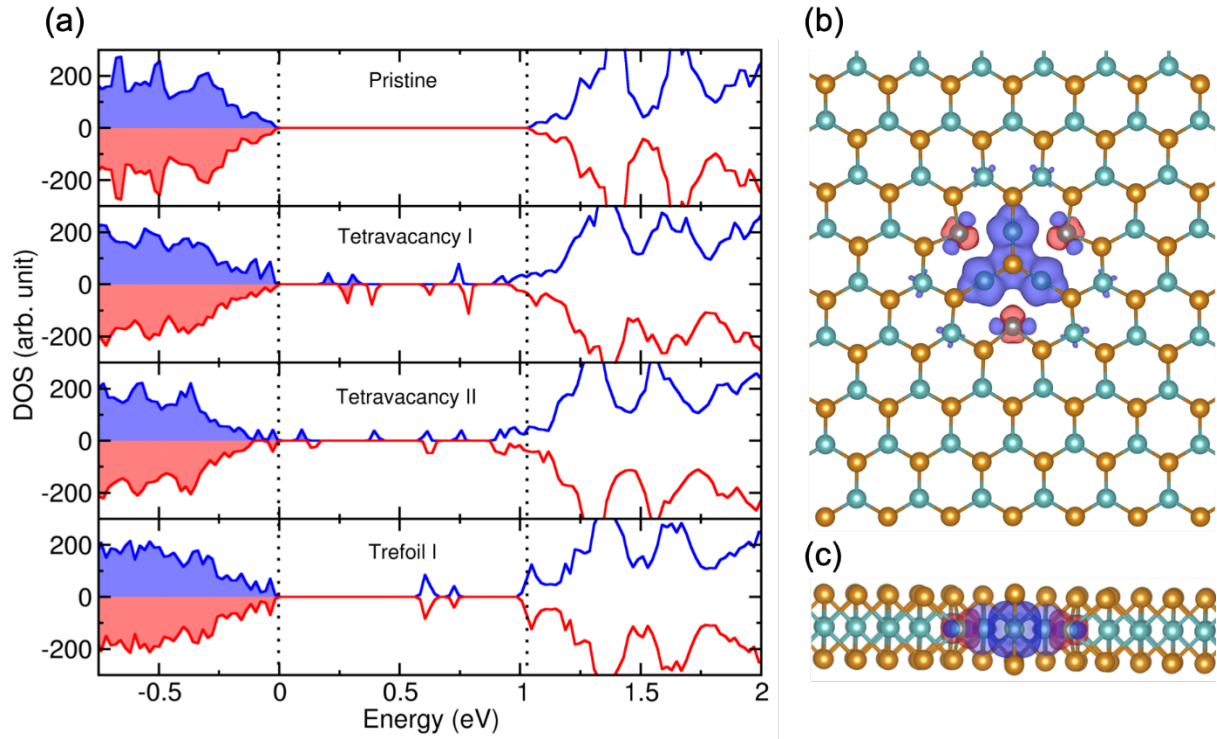

Figure 4: (a) Spin-polarized total density of states for various point extended defects in MoTe₂. The dotted lines show the band edges of the pristine system. (b, c) Majorities/minority spin density of Tetravacancy I, defined as $\rho_{\text{up}} - \rho_{\text{down}}$, where ρ_{up} and ρ_{down} are spin-resolved charge densities for spin-up and down components, top (b) and side (c) views. Blue and red colors correspond to majority/minority spin densities, respectively. The isosurface was set to $0.002 \text{ e } \text{\AA}^{-3}$. The magnetic character of the Tetravacancy I and II defects are clearly observable due to the asymmetric spin polarization effect in the band gap region.

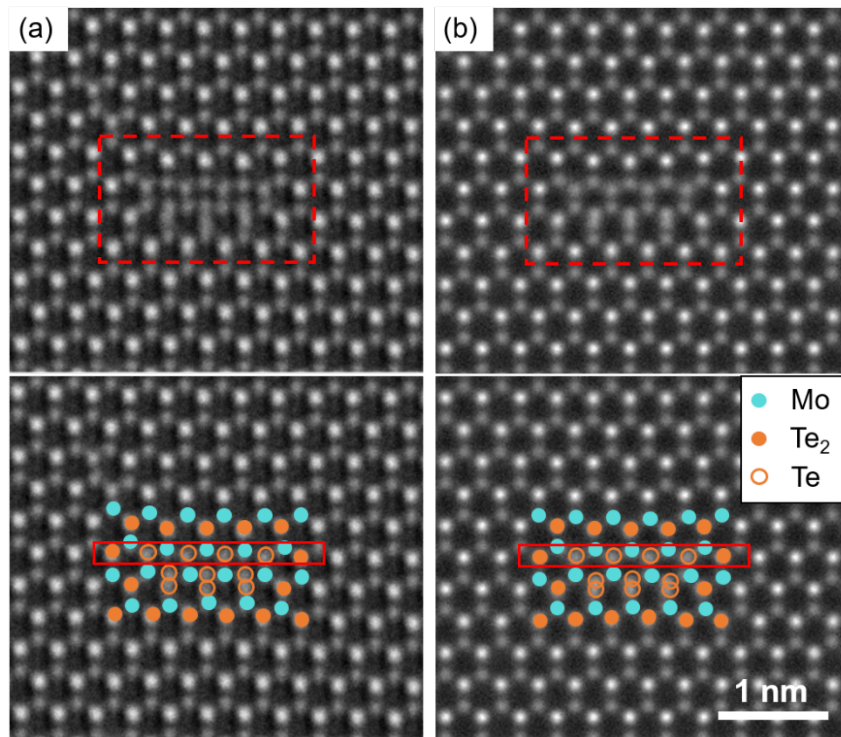

Figure 5: 40 kV Cc/Cs-corrected HRTEM images of an experimental (a) and a simulated (b) single vacancy line with four missing Te atoms seen within the dashed frame in the upper images (and framed by their solid rectangular in the lower images). In the lower panels, atoms in the areas marked in upper image are highlighted with different colors: solid, orange dots mark two stacked-up Te atoms, orange rings mark one Te atom and the turquoise solid dots mark Mo atoms.

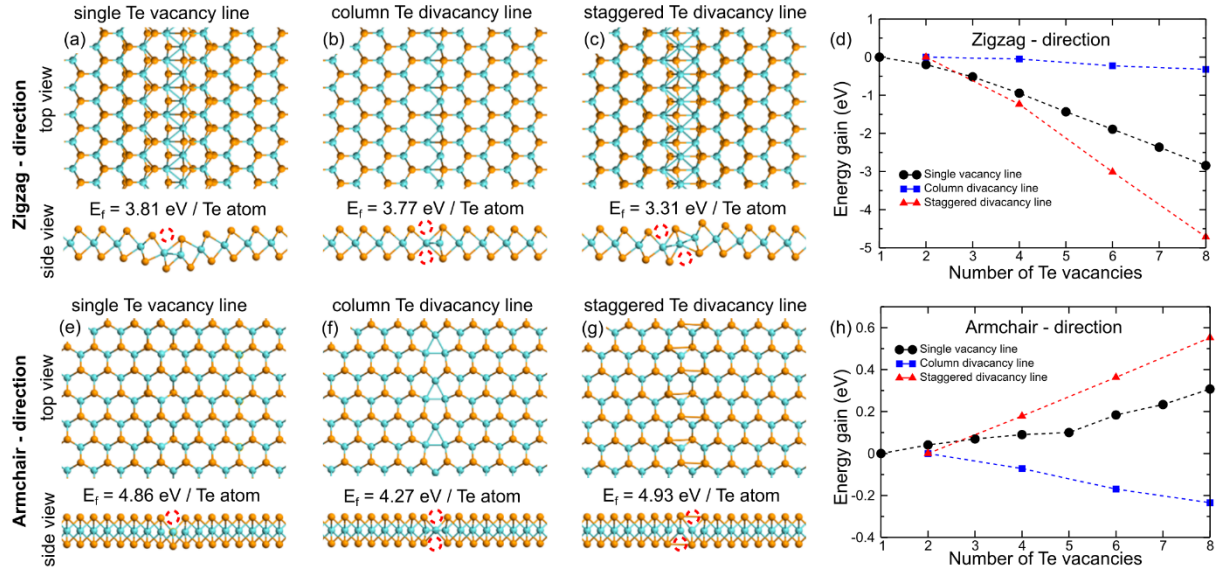

Figure 6: DFT calculations for vacancy lines. In (a) – (c), vacancy line structures oriented in zigzag direction and the corresponding formation energies E_f are presented. The energy gains upon forming extended defect from isolated vacancies are shown in (d) for vacancy lines of different lengths. The single vacancy line is energetically favorable up to a length of three vacancies, and afterwards the staggered divacancy line has lower energy. The structure of vacancy lines and their formation energies in armchair direction are given in (e) – (g). In the side view of the atomic structures, the red dashed rings indicate the positions of the missing Te atoms. Panel (h) shows the energy difference for the agglomerated lines in armchair directions. The only model, which yields energy gain upon agglomeration of vacancies is the column divacancy line.

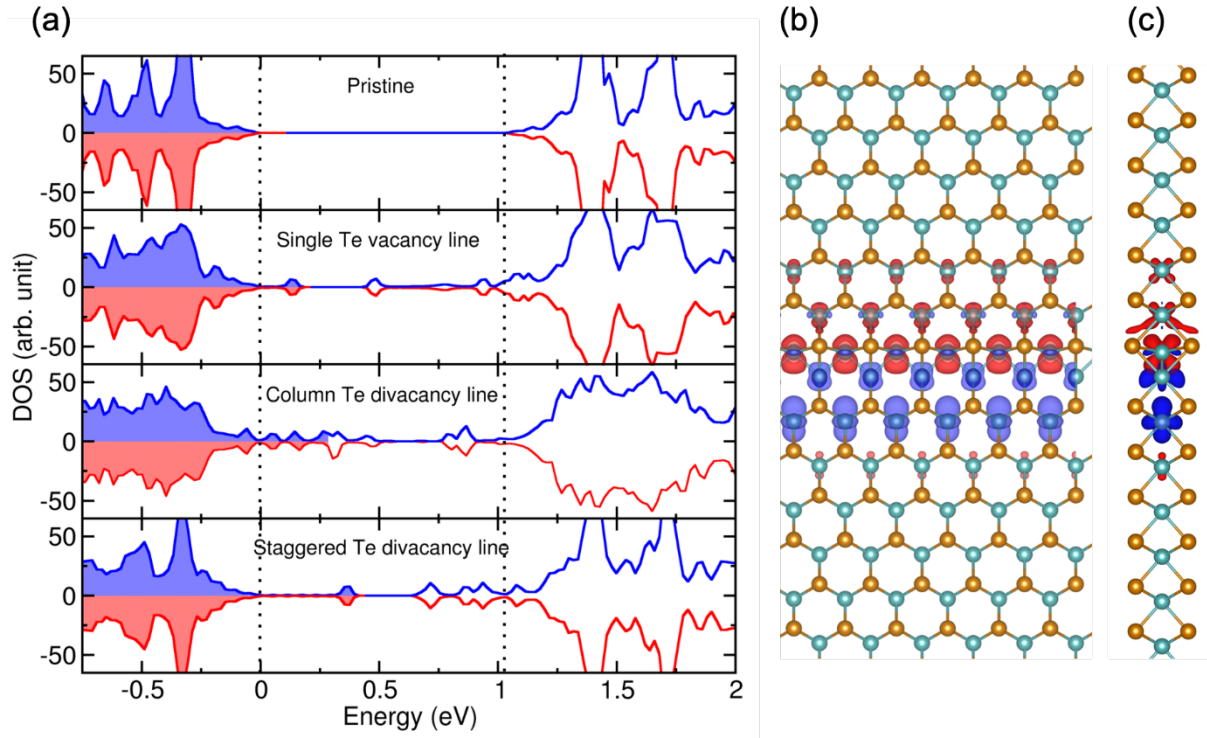

Figure 7: (a) Spin-polarized total density of states for various line defects in MoTe₂. The defect structures are oriented along the zigzag direction. The dotted lines show the band edges of the pristine system. (b, c) Spin density in column Te divacancy line. Blue and red colors correspond to the majority/minority spin densities, respectively, top (b) and side (c) views. The isosurface was set to $0.0003 \text{ e } \text{\AA}^{-3}$.

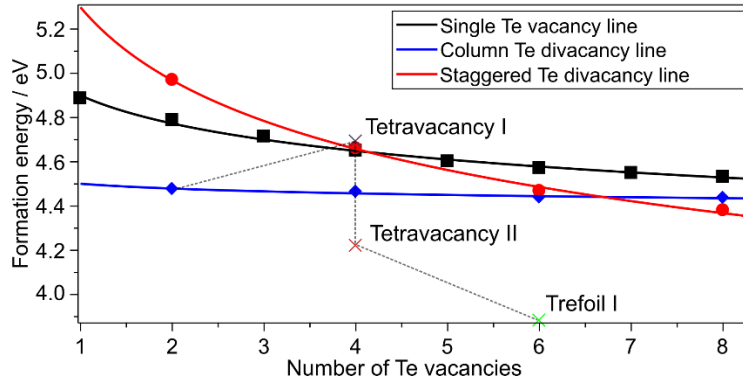

Figure 8: Formation energies of Te vacancy lines and extended defects as functions of the number of Te vacancies. A dashed path is added to illustrate and guide the eye along the agglomeration process of column Te divacancies.

Figure 9: 40 kV HRTEM images of inversion domains (a) – (c). In panel (a), the arrows indicate the corners of the inversion domain. The type of the MTBs is marked in (b) with the red lines and correspond to 4|4P and 4|4E boundaries. In (c) the atoms are marked with different colors: solid

orange for Te_2 and solid turquoise for Mo atoms. The images (d) –(f) show a local phase transformation from the 2H to 1T' phase. The atom migration indicated by white arrows is induced by a strain of a single Te vacancy line, located between the red arrows (d). Image (e) show the 1T' phase. The white trapezoidal frame clarifies that the vacancy line is moved and it is shorter after the transformation. In (f) the atoms are again colored for better visualization.
