Abstract

The Lower Group chromitites of the Bushveld Igneous Complex are mined for chromite as a primary product. The recovery of platinum group elements and base metals (Ni, Cu) as by-products has the potential to add value to the chromite resources. This study focuses on the LG-6 and LG-6A chromitite seams at the Thaba mine located on the western limb of the Bushveld Complex. Platinum group minerals and base-metal sulfides are studied by mineral liberation analysis and electron microprobe analysis to define distinct assemblages and to evaluate the potential for beneficiation. Based on the results two distinct major mineral assemblages are defined: The first assemblage is rich in platinum group element-sulfides, along with variable proportions of malanite/cuprorhodsite and alloys of Fe and Sn. The associated base metal sulfides are dominated by chalcopyrite and pentlandite, along with pyrite and subordinate millerite/violarite. Associated silicates are mainly primary magmatic orthopyroxene and plagioclase. The second assemblage is rich in platinum group element-sulfarsenides and -arsenides as well as -antimonides and -bismuthides, which are associated with a base metal sulfide assemblage dominated by pentlandite and Co-rich pentlandite. The assemblage is also marked by an abundance of alteration minerals, such as talc, serpentine and/or carbonates, which are closely associated with the platinum group minerals. Statistical evaluation reveals that these two mineral assemblages cannot be attributed to their derivation from different chromitite seams, but document the effects of pervasive hydrothermal alteration. Alteration evidently had similar effects on the different chromitite seams. The occurrence and distribution of the two characteristic assemblages has important implications for beneficiation. Assemblages rich in platinum group element-sulfides associated with base metal sulfides respond well to flotation, different to alteration assemblages rich in arsenides, antimonides and bismuthides. The nature of the gangue minerals will also impact platinum group mineral recovery as high phyllosilicate abundances, such as that encountered in the alteration assemblage may cause problems during flotation and lead to poor recoveries.

Keywords: SEM-based image analysis, ANOVA, Cluster Analysis, PGM, Thaba Mine, Bushveld Complex, EPMA

Introduction

The Bushveld Igneous Complex in South Africa is the world's largest layered mafic-ultramafic intrusion. The Rustenburg Layered Suite (RLS), comprising the most significant portion of the Bushveld Complex, consists of 7.5 to 9 km thick mafic and ultramafic cumulate rocks, covering an area of approximately 65,000 km^2. The RLS was emplaced approximately 2,056 Ma ago (2,055.91±0.26; Zeh et al. 2015) and can be subdivided into the Marginal, Lower, Critical, Main, and Upper Zones (Hall 1932, Figure 1A).

The RLS hosts 21 chromitite seams (*e.g.*, Fourie 1959; Naldrett et al. 2012; 16 are shown in Figure 1B). According to their stratigraphic position these are subdivided into lower, middle and upper group chromitites. The Lower Group (LG) and Middle Group (MG) chromitites are extensively mined for chromite as a primary product (*e.g.*, the mines Doornbosch, Winterveld, Lannex, Tweefontein and Dwarsrivier; DERA 2013). The uppermost of the chromitite seams (UG-2), in contrast, is exploited for platinum-group elements (PGE) as the primary economic product as it reaches PGE concentrations up to 10 ppm Σ[PGE+Au] (Von Gruenewaldt et al. 1986; Lee 1996; Cawthorn 2011). Base metals and chromite are recovered from the UG-2 as by-products. Whilst all other chromitite seams do also contain elevated PGE concentrations, these range only from 0.5 to 3 ppm (Wagner 1929; Von Gruenewaldt 1977; Von Gruenewaldt et al. 1986; Lee and Parry 1988; Cawthorn 1999; Barnes and Maier 2002; Naldrett et al. 2009a; Naldrett et al. 2012). Additionally, the chromitites display a progressive increase in PPGE (Pt+Pd+Rh) from the LG to the UG chromitites, whereas the content of IPGE (Os+Ir+Ru) remains broadly constant or increases only slightly (Naldrett and von Gruenewaldt 1989; Scoon and Teigler 1994; Naldrett et al. 2009b). This trend coincides with decreasing Cr/Fe ratios of the chromitites and results in a focus of mining the MG and LG seams for chromite (DERA 2013). The exploitation of PGE in the MG and LG seams is currently regarded as sub-economic (Oberthür et al., 2016).

Published knowledge on the mineralogy and deportment of PGE and base metals in the LG chromitite seams is scant (Teigler and Eales 1993; Scoon and Teigler 1994; Naldrett et al. 2009b, 2012; Junge et al. 2016; Oberthür et al. 2016) and beside the investigation of Maier and Barnes (Maier and Barnes 1999, and references therein) at Union Section, only scarce information is available in particular for the northern part of the western limb of the Bushveld Complex. The UG-2, in contrast, has been investigated in great detail (*e.g.*, McLaren and De Villiers 1982; Gain 1985; Hiemstra 1985, 1986; Maier and Barnes 2008; Cawthorn 2011; Junge et al. 2014, 2015; Osbahr et al. 2014). Junge et al (2016) and Oberthür et al. (2016) emphasized the similarity of PGM of the LG-6 with the UG-2 chromitite. However, with samples derived for these studies from reworked chromite dumps, they may yield representative results but lack any geological context. Given the scarcity of published data, it is not surprising that the mechanism of PGE enrichment in chromitite seams remains a subject of debate. Controversial aspects include the sulfide-poor nature of the RLS (S contents commonly < 100 ppm; Scoon and Teigler 1994), and the presence of discrete PGM containing almost the entire budget of PGE (*e.g.*, Hiemstra 1986).

Studies on the beneficiation characteristics of PGM and base metal sulfides (BMS) in Bushveld chromitite seams other than the UG-2 are very scant – as most published contributions focus on those resources currently exploited (UG-2, Platreef and Merensky Reef) (*e.g.*, Penberthy et al. 2000; Bulatovic 2003; Shackleton et al. 2007a,b; Brough et al. 2010; Becker et al. 2008; Chetty et al. 2009, Voordouw et al. 2010, Bushell 2012, Smith et al. 2013, Becker et al. 2014). These studies confirm that characteristics such as quantitative mineralogy, deportment, mineral association and grain sizes play a major role in PGM beneficiation. The type of PGM species, their liberation and association are particularly relevant for floatability (*e.g.*, Penberthy et al. 2000; Chetty et al 2009) as well as the association of PGM with BMS (Xiao and Laplante, 2004). PGM association with gangue minerals displays a separate set of challenges for flotation processes (*e.g.*, Chetty et al. 2009). Furthermore, Penberthy et al. (2000) reported that the grain size of PGM also affects floatability, with very fine (*i.e.* <3 μm) PGM considered as slow floaters.

99 Despite these constraints a possible recovery of base metals and PGE as by-product during
100 exploitation of chromite would certainly add value and increase resource efficiency of chromite
101 mining ventures. A successful example in this regard is Sylvania Platinum Ltd., reworking chromite
102 dumps of the LG-6 and MG-1/2 chromitites from the eastern and western Bushveld Complex and
103 producing saleable concentrates of both PGE and chromite (Junge et al. 2016; Oberthür et al. 2016).

104 This study focuses on the LG-6 and LG-6A chromitite seams located at the Thaba mine, a chromite
105 mine situated on the western limb of the Bushveld Complex (Figure 1A) that is operated by Cronimet
106 Chrome Mining SA (Pty) Ltd., a subsidiary of the Cronimet Mining Group. The proven reserves at
107 Thaba total 23.6 Mt of chromite ore at 43.6 wt% Cr_2O_3 resulting in ca. 10 Mt contained Cr_2O_3 (DERA
108 2013). Mining started in 2011 and the life of mine is estimated at 26 years (DERA 2013). The mine
109 exploits the LG-6/LG-6A as well as the MG-1 to MG-4A chromitite seams. Any PGE recovery needs to
110 follow, or be integrated with, the recovery of chromite as the primary product.

111 In the present study, samples were obtained from three drill core intersections of the LG-6 and LG-6A
112 chromitites at Thaba mine. The aims of the study are:

113 (i) to characterize the PGM and base metal sulfide and Fe-sulfide (BMS) assemblages by *in-*
114 *situ* analysis of polished thin section surfaces of LG-6/LG-6A chromitite using scanning
115 electron microscopy–energy dispersive X-ray spectrometry (SEM-EDS)-based image
116 analysis techniques, complemented by electron microprobe analysis (EPMA),
117 (ii) to provide data on the composition of major silicate minerals and chromite,
118 (iii) to relate observed systematic changes in mineralogy and mineral association to
119 geological processes,
120 (iv) to discuss the obtained data with respect to published work and to assess implications
121 for the beneficiation of the chromitite ores.

The results are used to constrain the nature, distribution and origin of PGM and BMS in the chromitites of the RLS. Furthermore, our study provides important constraints for eventual beneficiation, as we consider not only qualitative mineralogy and mineral assemblage, but also quantify relevant attributes such as mineralogy, mineral grain sizes and mineral association for PGM and BMS. The *in-situ* methodology approach used in this study is preferred compared to the more widely employed method of studying grain mounts of PGM concentrates (*e.g.*, Junge et al. 2016; Oberthür et al. 2016) as it eliminates limitations to produce statistically significant results, for parameters such as mineral association, as shown elsewhere (*e.g.* Penberthy et al. 2000; Voordouw et al. 2010; Viljoen et al. 2012; Smith et al. 2013).

Analytical Methods

Access to diamond drill core intersections of LG-6 and LG-6A chromitite seams at Thaba mine was granted by Cronimet Mining Group. Drill cores were logged to document the lithological architecture of each intersection. Quarter drill cores were sampled with the goal to sample "pristine ores" below the extent of present-day weathering, *i.e.* to depth in excess of 50m below the present-day land surface, across the mine lease area. This approach was successful as none of the studied samples revealed any evidence of supergene oxidation of BMS. Six different drill core locations were selected for this study (Table 1), three of them for sampling of LG-6 (EL28, ZK149, ZK144) and three for LG-6A (EL32, ZK136, SC42). Deflections were considered wherever available. Samples from deflections are always demarcated by adding a D to the drill hole location name (Table 1). Chemical assay data for some of the selected drill cores were made available by Cronimet Mining Group. Available assay data refer always to entire chromitite seams; no assay data were available for drill cores ZK144, EL32D, and ZK136D.

The general sampling approach follows that of Voordouw et al. (2010). To investigate, if the LG-6 is bottom- or top-loaded with respect to PGM and BMS, each drill core intersection was divided into five distinct sectors: sector 1 covers the bottom 10%, sector 3 the mid 40% and sector 5 the top 10%

of the seam (sector 2 and 4 are each 20 %). Each sector was sampled randomly to prepare an individual polished thin section for study.. A similar approach was applied to the sampling of the LG-6A, but samples of sector 1 and 5 were set onto the contact between host rock and chromitite wherever this was possible. This resulted in a higher overall silicate proportion in the modal mineralogy than for the LG6 samples. Each section was cut vertical to stratigraphy.

Mineral Liberation Analysis (MLA)

Thirty polished thin sections of ca. 150 µm in thickness were prepared at the Helmholtz Institute Freiberg for Resource Technology (HIF). Each of these sections was analyzed twice by MLA on two polished surfaces well-separated by re-grinding and re-polishing. These two surfaces are referred to as surface A and surface B; all data and detailed investigations on the reproducibility of the MLA measurements can be found in the electronic supplementary material (Appendix A, B and C). The sections were analyzed twice to increase the number of PGM and BMS grains identified and to constrain intra-sample variation. Furthermore, two sample surfaces were analyzed as in-run duplicates to check for internal consistency of data acquisition.

The MLA instrument used in this study is located at the HIF and comprises a scanning electron microscope FEI Quanta 650F equipped with two Bruker Quantax X-Flash 5030 energy-dispersive X-ray spectrometers and the MLA 3.1.4 software suite for automated data acquisition. Consistent operating conditions were applied (Table 2). DataView (Fandrich et al. 2007) software was used for further processing of the data. All samples were analyzed using the sparse phase liberation (SPL_Lt) and the grain X-ray mapping (GXMAP) mode (Fandrich et al., 2007). Standard spectra were collected for all relevant minerals. Selected grains of silicates, BMS and PGM were then analyzed by electron microprobe (EPMA, see below). More detailed information about the functionality of a MLA and the joint offline processing of EPMA and MLA data can be found in Gu (2003) and Bachmann et al. (2017).

As shown by Voordouw et al. (2010), abundances of individual PGM, sulfides and silicates may differ from each other by an order of magnitude; the proportions of individual minerals are thus described within chemically similar groups rather than in absolute terms (*e.g.*, area%^{PGM} refers to the area% of individual PGM among all PGM).

Electron probe microanalysis (EPMA)

Electron probe microanalysis was performed with a JEOL JXA 8530F at the HIF equipped with a field emission electron gun and five wavelength dispersive spectrometers (WDS). Five different analyzer crystals TAP, PETJ, PETL, PETH, and LIFH on five spectrometers were utilized to measure chemical compositions of various base metal and iron sulfides (BMS) as well as PGM. Quantitative EPMA analyses were also performed on major silicates and chromite. Detailed information about the methodology and the entire data set is provided in the electronic supplementary (Appendix A and D).

The assignment of the analyzed elements to detector crystals and spectrometers as well as peak and background positions, dwell times and the lower limit of detection during PGM and BMS analyses are shown in Table 3. All quantitative analyses were performed with a focused beam at an accelerating voltage of 12 kV/ 20 kV and a beam current of 100 nA/ 30 nA. Analyses were corrected according to the measurement protocol of Osbahr et al. (2015), slightly modified by a time-resolved offline overlap correction and a step-wise overlap correction of multiple interferences. EPMA results were further used to generate mineral standard spectra with a known composition for MLA measurements.

Statistics

Statistical data evaluation and comparison of properties across the data set was obtained via ANalysis Of VAriance (ANOVA, *e.g.* Fahrmeir and Hammerle, 1984), which explains the variance of several target (predicted) variables by the influence of certain explanatory factors. In our case the modal mineralogy in respectively area%^{PGM}, area%^{BMS}, area%^{Gangue} (Gangue: alteration silicates, silicates, carbonates) are predicted variables. Other minerals occurring in trace quantities, such as

196 monazite, zircon, etc, were not considered as they add no relevant information. Chromite was not
197 considered because the chromite content is strongly dependent on the sampling location, *i.e.*
198 massive chromitite, chromitite with silicate intercalations or chromitite – host rock contact.
199 Explanatory factors considered were: The section surface (A/B), the relative stratigraphic position
200 within a seam "intra seam" (top, top-middle, middle, bottom-middle and bottom), and either the
201 seam (LG-6 vs. LG-6A) or the borehole (EL28D-LG-6, ZK149-LG-6, ZK144-LG-6, EL32D-LG-6A, ZK136D-
202 LG-6A vs.SC42-LG-6A, "inter-core" effects). ANOVA allows to test in an organized manner, which of
203 these variables exert a significant, systematic control on the area% composition of the mineral
204 groups considered. This is achieved by F-tests targeting each explanatory variable, and checking the
205 null hypothesis that the residual variability of a model including that target variable is the same as a
206 model without it. If this would be the case, then the target variable would not reduce the uncertainty
207 about the explained composition, and should be discarded. In practical terms, for those variables for
208 which the F-test returned a significance level of $p < 0.05$, the null hypothesis is rejected, hence the
209 target variable is accepted as having a significant influence on the composition. Significance levels
210 considered are: 0-0.001 highly significant, 0.001-0.01 moderately significant, 0.01-0.05 significant,
211 0.05-1 not significant.

212 A cluster analysis for the mineral association of PGM and BMS was performed to support the
213 separation into distinct ore types suitable for further treatment in a mineral beneficiation process.
214 The R software environment (R Core Team 2016) with the additional packages "mclust" (Fraley and
215 Raftery 2002) and "compositions" (van den Boogaart et al. 2014) were used for data analysis. The
216 algorithm "mclust" requires a choice of the characteristics (orientation, size and shape) of the
217 covariance matrix which are allowed to vary between groups: the analysis was done in "VVV"-mode,
218 meaning that each cluster was allowed to have a totally different covariance matrix (Fraley et al.
219 2012). All modal mineralogy subcompositions were treated with the statistical framework of
220 compositional data analysis (Aitchison, 1986; Tolosana-Delgado, 2012), to avoid the effects of

spurious correlation occurring in such closed subcompositions (Chayes, 1960). To get rid of these effects, the solution chosen here is to work with ratios or log-ratios between components.

Results

Results are presented in three sections. The first provides a brief description of the lithological architecture and qualitative petrographic appearance of the LG-6 and LG-6A chromitite seams sampled. The following section reports the results of EMP analysis, *e.g.* the mineral chemistry of PGM and BMS. This data is complemented by analyses of silicates and chromite provided in the electronic supplement (Appendix A). Finally, MLA results are evaluated in terms of modal mineralogy (sub-compositions PGM/BMS/Gangue as defined above) and mineral association (PGM/BMS).

Lithology and Mineralogy

This section provides largely qualitative descriptions of the studied chromitite seams – and their mineralogy. Quantitative mineralogical data is provided later in this contribution. The LG-6 and LG-6A chromitite seams at Thaba mine are well developed as massive, single seams that are usually hosted by pyroxenite. The LG-6 seam as the primary mining target averages 0.85 m in thickness, varying between 0.34 m and 1.37 m; the Cr_2O_3 content averages 43.1 % and the Cr:Fe ratio is 1.58. The LG-6A occurs stratigraphically approximately 6 m above the LG-6 seam and averages at 0.23 m in thickness, containing on average 41.2 % Cr_2O_3 with a Cr:Fe ratio of 1.48. Locally, cm-thin chromitite stringers (such as in sample EL028-LG-6) or pegmatoidal pyroxenite (ZK136-LG-6A and EL32D-LG-6A) occur in the pyroxenite host rock. Footwall (0.2 m) and hanging wall (1 m) of EL32D-LG-6A consist of serpentinite (altered pyroxenite) while some of the pyroxenite in intersection ZK149-LG-6 is also strongly serpentinized.

All chromitite samples selected for this study are best described as massive chromitites that are comprised mostly of chromite, orthopyroxene and plagioclase. Thin intercalations of silicate rocks as well as up to a few cm long silicate oikocrysts are locally common in these massive chromitites.

Chromite grains are subspherical in shape, with average diameters of < 0.5 mm (max. ~1 mm), and smooth grain margins. Chromite grains may host inclusions of silicates, sulfides and Fe-Ti oxides. Subvertical veinlets are common, containing variable amounts of mica, amphibole and minor carbonates. Especially in sample EL32D-LG-6A, chromite grains appear fractured and are cemented by a younger generation of chromite.

The silicate minerals have been subdivided into two assemblages. The first assemblage includes silicates regarded as orthomagmatic in origin (called silicates group), the other assemblage includes all (hydrous) silicates that are considered to have formed by post-magmatic hydrothermal alteration (called alteration silicates group). The silicates group is dominated by pyroxene (more orthopyroxene than clinopyroxene), followed by feldspar, and traces of olivine, while quartz is almost absent. Mica is present in very minor abundances and is biotitic in composition. Feldspar compositions are dominated by plagioclase, alkali feldspar occurs only in trace amounts. In intersections ZK149-LG-6 and EL32D-LG-6A, feldspar is entirely absent.

The alteration silicates group is dominated by amphibole, chlorite (mainly clinochlor) and talc, while only minor serpentine is present. Carbonate minerals (mainly of dolomitic compositions) were also identified as part of the hydrothermal alteration assemblage and occur only in very minor amounts. A notable exception is the occurrence of dolomite in chromitite seam LG-6A of drill core EL32D.

PGM and BMS occur in all samples in trace amounts. PGM are observed as monomineralic grains, which may show internal zonation, but also as aggregates of variable complexity (for representative examples see Figures 2B-H). Equivalent circle diameters (ECDs, value of the diameter of a circle having the same area as the measured grain/particle; *e.g.*, Fisher et al. 1987) of PGM grains/ aggregates typically range between <1 and 20 µm, ECDs of up to 35 µm are scant. Average ECDs are consistently between 4 µm and 5 µm. PGM are often locked or attached to BMS but also occur enclosed in or interstitial to chromite, silicates and alteration silicates. PGM enclosed within chromite grains consist mainly – but not exclusively - of laurite (Figure 2G). Members of the laurite [RuS_2] -

erlichmannite [OsS_2] series are also the main carriers of IPGE (iridium-subgroup; Ir, Ru, Os). Minerals belonging to the cooperite-braggite-vysotskite [PtS – (Pt,Pd)S – PdS] series and members of the thiospinel solid solution series malanite [$CuPt_2S_4$]-cuprorhodsite [$CuRh_2S_4$] are major carriers of the PPGE (platinum subgroup; Pt, Pd, Rh). Sperrylite [$PtAs_2$], PGE-antimonides, -bismuthides and -bismuthotellurides such as geversite [$PtSb_2$], and stibiopalladinite [$Pd_{5+x}Sb_{2+x}$] with minor sudburyite [PdSb], insizwaite [$PtBi_2$], and traces of genkinite [$(Pt,Pd)_4Sb_3$] and moncheite [$(Pt,Pd)(Te,Bi)_2$] are of lesser abundance as are PGE-alloys including rustenburgite [Pt_3Sn] and tetraferroplatinum [PtFe]. Traces of native platinum [Pt] were also identified. Sulfarsenides (platarsite [PtAsS], hollingworthite [RhAsS] and irarsite [IrAsS]) with variable compositions contribute significantly to the overall PGE budget in some samples.

BMS usually occur as aggregates up to 300 µm in diameter or as single grains (<100 µm), interstitial to chromite or enclosed in silicates. Smaller (up to 100 µm) aggregates of BMS were found as inclusions in chromite. Importantly, pyrrhotite is almost absent. In general, BMS are dominated by pentlandite [$(Ni,Fe)_9S_8$], which in some cases contains minor concentrations of Co. Other important Ni-sulfides are millerite [NiS] and violarite [$Fe^{2+}Ni_2{}^{3+}S_4$]. Violarite often rims and replaces pentlandite (Figure 2A, D). Some examples of millerite and violarite do also contain minor amounts of Co. Chalcopyrite and pyrite only occur in some samples in significant amounts – relative to the other BMS. Galena, stibnite and sphalerite were detected only in negligible abundance – they are not considered further.

Geochemistry and Mineral Chemistry

5PGE+Au (Pt,Pd,Rh,Ir,Ru,Au) contents are around 1 ppm for LG-6 samples and 1.5 ppm for the LG-6A, with a Pt/Pd ratio around 2.2 and 4 and Pt/Ru ratios around 0.9 for intersections ZK144-LG-6 and ZK149-LG-6, respectively. In general, the total sulfur content ranges between 100 – 200 ppm (<250 ppm), except intersection ZK144-LG-6, which contains only around 70 ppm. Arsenic contents

294 are usually below the detection limit (<0.5 ppm), except in a few samples of ZK149-LG-6 (up to
295 9 ppm). Detailed data is provided with the electronic supplement (Appendix A and E).

296 Mineral chemistry data was obtained for all relevant rock-forming mineral groups, except chlorite
297 and mica. Pyroxenes, amphiboles, serpentine and talc, as well as chromite compositions are well
298 discriminated by their mineral chemistry. Two different types of pyroxenes were detected, an
299 orthopyroxene (hereafter referred to as enstatite with Mg/ ($Mg+Fe^{2+}$) ratios ranging from 0.82-0.84)
300 and a clinopyroxene with augitic to diopsidic composition (hereafter referred to as diopside).
301 Amphiboles can be best described as magnesio-hornblende. Feldspars yield plagioclase compositions
302 (Median = An_{66}). In general, chromite displays $Mg/(Mg+Fe^{2+})$ cation ratios around 0.42 (sample
303 EL32D-LG-6A around 0.33), while Cr/(Cr+Al) cation ratios plot at 0.73 (EL32D-LG-6A: ~0.64). Detailed
304 data and methodology are provided in the electronic supplement (Appendix A and D).

305 The composition of PGM and BMS is collated in Tables 4 and 5. Mineral chemistry data were used to
306 provide proper identification of PGM in MLA data sets – and to characterize BMS in greater detail.
307 Pentlandite displays rather variable compositions, especially regarding the concentration of Co. For
308 the purpose of this study we refer to pentlandite containing > 2 wt% Co as Co-rich pentlandite. Pyrite
309 analyses reveal Co and Ni contents up to 1.5 wt% and 3.5 wt%, respectively.

310 A notable number of pyrite, pentlandite, Co-rich pentlandite and violarite analyses as well as a few
311 chalcopyrite analyses yielded measureable PGE concentrations. Pyrite, pentlandite and Co-rich
312 pentlandite yield concentrations up to 2-3 wt% Rh, Pt, Ru and Ir, around 1 wt% Pd and up to 0.5 wt%
313 Os. Chalcopyrite was found to contain PGE contents below 1 wt% and violarite up to 0.4 wt% Rh and
314 0.2 wt% Pd, respectively. Despite the fact that several previous studies have suggested that BMS can
315 contain significant amounts of PGE (Osbahr et al. 2013; Osbahr et al. 2014; Junge et al. 2014), the
316 concentrations reported in this study are unusually high. We tentatively consider the PGE as being
317 localized as submicroscopic inclusions of discrete PGM in the BMS (see Figure 2H), occasionally hit by
318 spot analyses during the EPMA measurements.

Quantitative Mineralogy and Microfabric Data

Quantitative mineralogical and microfabric data were obtained by MLA analysis. In order to facilitate comparison, the rock-forming minerals were grouped as follows (sorted by abundance): Chromite (Al-rich spinel, various chromite compositions), silicates (ortho- and clinopyroxene, feldspar, olivine, quartz, biotite), alteration silicates (amphiboles, chlorite, muscovite, serpentine, talc), carbonates (calcite, dolomite), others (*e.g.*, apatite, barite, monazite, rutile, titanite, zircon). For PGM and BMS compositional sub-groups were defined (Table 6). The relative abundance of these is expressed as area%^{PGM} and area%^{BMS} – this was done to ease comparison between different samples. The same was done for gangue mineral groups (alteration silicates, silicates, carbonates) – these are expressed as area%^{Gangue}.

The quantitative mineralogy of all sampled seams is given in Table 7. For this purpose, data obtained for all five samples collected from each seam was combined. Data for PGM and BMS for every thin section surface analyzed is provided in the electronic supplement (Appendix C). This investigation uses relative abundances of different PGM subgroups for classification. As illustrated in Figure 3A, minerals belonging to the (Ru,Ir,Os)S_2 subgroup are present in all samples, but comprise rather different proportions of the total PGM population (LG-6: 17 up to 59 total area%^{PGM}; LG-6A: 6 up to 64 total area%^{PGM}). In samples El28D-LG-6, ZK144-LG-6, ZK136D-LG-6A and SC42-LG-6A (Pt,Pd)S and (Pt,Rh)$_2$$CuS_4$ are common PPGE carriers subordinate only to alloys containing Fe and Sn; the latter range from 30 to 68 total area%^{PGM} in the LG-6 and from 33 to 65 total area%^{PGM} in the LG-6A seam. (Pt,Rh)$_2$$CuS_4$ is the dominant PPGE carrier in ZK144-LG-6. In contrast, the PGM assemblage in samples ZK149-LG-6 and EL32D-LG-6A is dominated by (PGE)As,AsS and (PGE)Sb,Bi, comprising 44 to 76 total area%^{PGM} in ZK149-LG-6 and 53 to 85 total area%^{PGM} in EL32D-LG-6A.

The BMS mineralogy is dominated by Co-rich pentlandite, chalcopyrite, millerite, violarite and pyrite as well as traces of pyrrhotite (Figure 3B). The sulfide proportions are highly variable. In samples ZK149-LG-6 and EL32D-LG-6A Co-rich pentlandite represents the majority of the BMS, while

chalcopyrite, pyrite as well as minor millerite dominate sample ZK144. Samples EL28D, ZK136D and SC42 contain variable proportions of Co-rich pentlandite, chalcopyrite, pyrite/ (pyrrhotite), violarite and minor millerite.

Figure 3C displays the relative distribution of PGM and BMS of intersections of the LG-6 and LG-6A seams. While ZK144-LG-6 has a rather low BMS content and an assemblage dominated by chalcopyrite and minor millerite, both Co-rich pentlandite dominated intersections (ZK149-LG-6 and EL32D-LG-6A) display a high sulfide content (resulting in a distinctly higher sulfur content, *i.e.* sample ZK149-LG-6 compared to sample ZK144-LG-6). In contrast, the PGM contents are rather similar, with somewhat lower abundances in EL28D-LG-6 and EL32D-LG-6A and distinctly higher PGM contents in sample ZK144-LG-6.

Statistical Assessment

The application of statistical methods is needed to deal with the large number of samples and the multivariate datasets. This leads to the differentiation of three substantially distinct PGM-BMS assemblages:

(I) PGM-sulfides and alloys of Fe and Sn ± PGM-Cu-sulfides occur together with a BMS assemblage dominated by pentlandite + chalcopyrite + pyrite

(II) PGM-Cu-sulfides ± PGM-sulfides ± alloys of Fe and Sn; corresponding BMS are dominated by chalcopyrite + pyrite + millerite ± pentlandite

(III) PGM-sulfarsenides and PGM-arsenides occur together with PGM-antimonides and -bismuthides and scant tellurides; corresponding BMS are strongly dominated by pentlandite and Co-rich pentlandite ± chalcopyrite ± pyrite.

The following sections document the relative contribution of ANOVA and cluster analysis to this result.

ANOVA

An ANOVA was performed – followed by standard F-tests – to investigate the variability of the samples and to determine assemblages for classification according to the sub-compositions area%^{PGM}, area%^{BMS} and area%^{Gangue}. Detailed results can be found in the electronic supplementary material (Appendix A). Results suggest that the "nugget effect" (small scale variability) is negligible for all sub-compositions. The variance between samples of a different stratigraphic position within a sampled seam, *i.e.* if seams have systematically different mineral assemblages within their respective confines, should be noted – but remains small. Furthermore, there are no systematic changes in mineral abundances observed between the two chromitite seams LG-6 and LG-6A. Thus, the variability between certain drill cores explains up to 80 % of the total variability – depending on the selected sub-composition. A detailed investigation of the ANOVA model showed a strong negative correlation of PGE -sulfarsenides and PGE-antimonides, -bismuthides vs. PGE –sulfides, -Cu-sulfides and -alloys of Fe,Sn (for area%^{PGM}), along with (Co-rich) pentlandite against the other four BMS considered, namely chalcopyrite, millerite, pyrite and violarite (for area%^{BMS}). Furthermore, a negative correlation of PGE-Cu-sulfides vs. PGE –sulfides and –alloys of Fe,Sn along with chalcopyrite and millerite against pyrite and violarite was observed. The area%^{Gangue} assemblages are best classified by separating alteration silicates and silicates-rich from carbonate-rich drill cores, followed by a separation of alteration silicates from silicate-rich cores. While carbonate-rich samples are associated with PGM-BMS assemblage (III), silicate-rich samples dominate PGM-BMS assemblage (I). Significant amounts of alteration silicates may occur in samples belonging to PGM-BMS assemblages (II) and (III).

Cluster analysis

For a quantitative assessment of the variability of the mineral association a cluster analysis was performed according to the sub-compositions of PGM (without IPGE sulfides) and BMS. The results were linked to the mineral assemblages defined in the previous chapter (*ANOVA*). Detailed information can be found in the electronic supplementary material (Apendix A). Despite the very low

394 total abundance of BMS (< 0.02 area% in all samples), PGM show a strong preferred association with
395 BMS; they also show a close association with alteration silicates, occurring both in interstitial
396 positions and as inclusion. PGM are only to a much lesser extent associated with silicates and
397 chromite. PGM occur predominantly interstitial to chromite (with minor inclusions cf. Figure 2G).
398 BMS show a very similar association to PGM.

399 **Discussion**

400 Appropriate statistical assessment of quantitative mineralogical data suggests the presence of three
401 distinct PGM-BMS mineral assemblages in the LG-6 and LG-6A chromitite seams at Thaba mine. The
402 LG-6 and LG-6A intersections show striking differences between different drill cores, resulting in
403 variable PGM, BMS, and gangue mineral assemblages. The (para)-genetic relevance of the
404 documented differences between these three assemblages is evaluated below. Finally, implications
405 for recovery of PGM and BMS are briefly discussed.

406 *General Aspects*

407 The LG-6/LG-6A chromitites at Thaba mine share numerous similarities to lateral equivalents at
408 other locations in the Bushveld Complex (e.g., Teigler and Eales 1993; Eales et al. 1993; Scoon and
409 Teigler 1994; Naldrett et al. 2009b, 2012). Such similarities include:

410 (1) chromitites are developed as single seams hosted by pyroxenite,
411 (2) Cr:Fe ratio is 1.58 for the LG-6 and 1.48 for the LG-6A, respectively,
412 (3) orthopyroxenes yield Mg/(Mg+Fe^{2+}) ratios ranging from 0.82-0.84,
413 (4) intercumulus feldspar compositions within pyroxenites in the Lower Critical Zone are those of
414 labradorite (Median = An_{66}),
415 (5) limited variation in chromite compositions,
416 (6) uniform PGE grades (5E + Au) around 1 ppm (LG-6) and 1.5 ppm (LG-6A),
417 (7) Pt/Ru ratios around 0.9, Pt/Pd ratios ranging from 2 to 4, and low S_{tot} ranging from 70 to
418 200 ppm.

We thus deem it likely that the observations made here can be transferred to other occurrences of LG chromitites within the Bushveld Complex.

Mineral assemblages

Different to previous investigations the present study offers quantitative mineralogical and microfabric data on *in-situ samples* (*i.e.* polished thin samples not modified by comminution or mineral separation) for PGM and BMS in the LG-6/LG-6A chromitites of the Bushveld Complex. The data provide unique insight into different PGM, BMS and rock-forming mineral assemblages and associations.

PGM assemblages are dominated by various Pt-Pd-Rh sulfides (cooperite-braggite and malanite-cuprorhodsite), laurite (the main carrier of the IPGE), sulfarsenides, sperrylite and Pt-Fe alloys; PGE-tellurides and PGE-bismuthotellurides are largely absent. These observations are rather similar to previous studies (*e.g.*, Junge et al 2016; Oberthür et al. 2016) carried out on mineral concentrates.

BMS occur only in very minor abundances. Pentlandite, Co-bearing pentlandite, chalcopyrite and pyrite dominate, whilst millerite is much less common. The virtual absence of pyrrhotite is noted. The BMS mineralogy is thus rather similar to that reported in previous studies for Bushveld chromitites (*e.g.*, Junge et al 2016; Oberthür et al. 2016).

Yet, despite these broad similarities, LG-6 and LG-6A chromitite intersections at Thaba mine reveal significant and systematic mineralogical variations that remained previously unnoticed. These mineralogical variations are observed in both the LG-6 and LG-6A – and can thus not be used to distinguish the two seams from one another. Rather, the differences need to be described as lateral variations independent of stratigraphic position.

Three different PGM-BMS assemblages were recognized (Figure 4):

(I) PGM-sulfides and alloys of Fe and Sn ± PGM-Cu-sulfides occur together with a BMS assemblage dominated by pentlandite + chalcopyrite + pyrite

(II) PGM-Cu-sulfides ± PGM-sulfides ± alloys of Fe and Sn; corresponding BMS are dominated by chalcopyrite + pyrite + millerite ± pentlandite

(III) PGM-sulfarsenides and PGM-arsenides occur together with PGE-antimonides, -bismuthides and scant -bismuthotellurides; corresponding BMS are strongly dominated by pentlandite and Co-rich pentlandite ± chalcopyrite ± pyrite

All three of these PGM-BMS mineral assemblages are interpreted to be the product of postmagmatic alteration, variably modifying an orthomagmatic assemblage.

Mineral assemblage (I) can be regarded as the most pristine assemblage, revealing a low alteration silicate to orthomagmatic silicate ratio. A relatively high BMS concentration and a variable PGM and BMS mineral association mark this assemblage. BMS display variable abundances of pentlandite, chalcopyrite, pyrite and minor violarite. PPGE carriers are PGE sulfides and PGE-Cu sulfides with variable proportions of PGE alloys of Fe and Sn. This is especially evident in intersection SC42-LG-6A, which contains significant amounts of violarite. While traces of millerite in EL28D-LG-6 and SC42-LG-6A as well as significant amounts of PGE alloys of Fe and Sn are consistent with beginning desulfidization, violarite is typically regarded as a product of late stage hydrothermal alteration of mixtures of iron-nickel sulfides (Dunn and Howes 1996; Tenailleau et al. 2006). Based on a statistical analysis a “typical” mineral association for PGM in assemblage (I) was defined. The dominating PGE-sulfides and -alloys of Fe and Sn are strongly associated to BMS and show only moderate affinity to silicates and alteration silicates (Figure 5).

Assemblage (II), best typified by sample ZK144-LG-6, is marked by the abundance of alteration silicates, although the alteration silicate to silicate ratio remains moderate. The total BMS content in assemblage (II) is rather low, as is the total sulfur content (~70 ppm). The BMS assemblage is

dominated by chalcopyrite, pyrite and millerite. Minerals of the malanite-cuprorhodsite solution series are by far the most important carriers for PPGE in this assemblage.

BMS and PGM present in assemblage (II) suggest an origin by removal of Fe and S by either late magmatic fluids and/or by reaction of sulfide with chromite from an orthomagmatic assemblage (e.g. Naldrett et al 2012 and references therein). The high amounts of Ni-rich sulfides are explained through re-equilibration of Fe from magmatic sulfide liquid with chromite (Naldrett and Lehmann 1988).

The high abundance of hydrous silicates associated with assemblage (II) suggests that corrosive action of hydrothermal fluids further modified the BMS assemblage. That these fluids may play a major role to explain the loss of sulfides was shown, for example, for the UG-2 (Penberthy and Merkle 1999; Li et al. 2004, Voordouw et al., 2010). High malanite-group PGM concentrations in chromitite were recently documented by Oberthür et al. (2016). The latter authors proposed that part of the orthomagmatic chalcopyrite experienced a similar fate as the re-equilibrated Fe-sulfides and has reacted to some extent with cooperite/braggite to form malanite. Although the PGM mineralogy displays some similarities with assemblage (I), such as a similar PGM spectrum, the mineral association of these PGM is distinctly modified and strongly dominated by alteration silicates, minor silicates and lack of association with BMS.

Mineral assemblage (III) is best represented by intersections ZK149-LG-6 and EL32D-LG-6A and can be further linked to gangue mineral assemblages. According to the ANOVA results, the gangue mineral assemblage is closely related to assemblage (II). However, assemblage (III) generally displays a significantly higher ratio in alteration minerals to orthomagmatic silicates; in drill core ZK149-LG-6 this is due to an abundance of alteration silicates, whereas in drill core EL32D-LG-6A carbonates are particularly widespread. Host rocks of these two intersections display strong serpentinization and thus provide further evidence for pervasive hydrothermal alteration. Furthermore, chromite analyses display somewhat higher $Mg/(Mg+Fe^{2+})$ and Cr/(Cr+Al) cation ratios (in sample EL32D-LG-6A). A

492 model including alteration by As-bearing fluids is favored over crystallization directly from As-bearing
493 melt as proposed by, e.g., Gervilla et al. (1996). Reasons for this interpretation include: (1)
494 Investigated samples have very low As contents and contain no other arsenides, such as nickeline,
495 etc., which would be expected in As-bearing melts. (2) PGE (sulf-)-arsenide-rich drill core
496 intersections display other prominent alteration features, as described above. (3) PGE arsenide-rich
497 assemblages of secondary origin are widely reported for the Bushveld Complex (Peyerl 1982; Kinloch
498 1982, Voordouw et al 2010). These arguments also support a secondary origin for PGE-antimonides
499 and –bismuthides. The PGE-(sulf)-arsenides, -antimonides and -bismuthides occur closely associated
500 with alteration silicates, carbonates or are interstitial to chromite. They show only a moderate
501 affinity to BMS and are almost absent as inclusions in chromite (Figure 5). Beside the carbonate-
502 dominated samples, the statistical assessment yielded similar results for the PGM mineral association
503 in assemblage (III) and assemblage (II), due to the strong affinity to alteration silicates. Nevertheless,
504 the low PGM affinity to silicates but higher affinity interstitial to chromite and to BMS, mainly
505 pentlandite, points to different processes responsible for the modification of the original
506 orthomagmatic mineral assemblage.

507 Laurite-group minerals, as the main IPGE carrier, deserve specific mention. They behave very
508 different to other PGM, and show stable proportions over all drill core intersections. According to the
509 statistical analysis laurite-group minerals remain unaffected by alteration processes. The same is true
510 for pyrite and pyrrhotite. Even though these two Fe-sulfides were reliably separated from
511 assemblage (III) in the ANOVA model, a further preferential association to assemblages (I) or (II) was
512 not possible to elucidate. This might be caused by the variable appearance of pyrite, as mineral of
513 primary (cf. Figure 2C) or possibly secondary origin (cf. Figure 2A, D), for example by replacing
514 pyrrhotite or as a by-product of the violarite alteration of pentlandite.

515

516

517 *Implications for beneficiation*

518 Given the fact that PGM and BMS were investigated *in-situ* in this study, the following relevant
519 parameters may be extracted and quantified from the data set for the potential recovery of PGM and
520 BMS: 1. Mineral species; 2. Mineral association; 3. Grain size distribution and 4. Gangue mineralogy
521 (*e.g.* Penberthy et al. 2000; Chetty et al. 2009). All these parameters are known to have a significant
522 impact on PGM recovery by flotation (*e.g.* Becker et al. 2013; Ndlovu et al. 2014).

523 Table 8 summarizes all relevant parameters of the three noted assemblages for mineral
524 beneficiation; similarities and differences between these assemblages are highlighted. Studies on the
525 floatability of different PGM species in the UG-2 chromitite (*e.g.* Penberthy et al. 2000; Chetty et al.
526 2009) suggest a higher floatability of sulfide-rich PGM assemblages compared to sulfarsenide-rich
527 assemblages. Flotation performance is also influenced by BMS and gangue mineralogy, as well as the
528 textural relations between PGM and associated minerals.

529 Relatively high recoveries may thus be expected for the BMS-rich assemblage (I), since the PGM
530 assemblage is not only sulfide-rich, but typically intergrown with a BMS assemblage marked by an
531 abundance of fast-floating chalcopyrite (Penberthy et al. 2000; Smith et al. 2013). In contrast, the
532 BMS content of assemblage (II) is significantly lower and PGM show rather little association to the
533 contained BMS. Therefore, recoveries of PGM may be expected to be somewhat lower, despite the
534 presence of PGM sulfides and chalcopyrite. Assemblage (III) can be expected to yield even lower
535 recoveries. This is due to the dominance of slow-floating sulfarsenides and a close association of
536 PGM with alteration silicates, chromite and carbonates – minerals that either do not float
537 (chromite/carbonate) or that need to be depressed in the given flotation process (*e.g.*, talc). The high
538 content of phyllosilicates in the alteration silicate association of assemblage (III) may be expected to
539 have rheological impacts in flotation, leading to even lower recoveries, as discussed by *e.g.*, Becker et
540 al. (2013) and Ndlovu et al. (2014).

In addition to the mineralogy of the three assemblages, the grain sizes of PGM and BMS will play an important role in defining recoveries during flotation. The average grain size of 4-5 µm ECD for the PGM and up to 300 µm ECD for BMS in all samples studied – irrespective of the actual assemblage. This suggests that PGM and BMS should be amenable to flotation, if fully liberated and not reduced further in size during comminution. PGM and BMS particle sizes <3 µm are generally considered to have poor flotation characteristics (Chetty et al. 2009). Nevertheless, to achieve sufficient liberation of the majority of the minute PGM grains will likely require fine milling – beyond the typical flotation feed of 45 – 80 % passing 75 µm typically used. However, the effects of ultrafine milling on liberation characteristics of PGM and BMS mineral grains and grain aggregates are beyond the purpose of this contribution. If PGM are associated with BMS – either because of intergrowth or because of the presence of minute inclusions of PGM – the grain sizes of PGM may in fact not be relevant for flotation - but rather the aggregate sizes and liberation of the BMS. These aggregates are typically larger than 30 µm, often up to a few 100 µm which will easily float and further improve PGE recovery.

Conclusion

Based on a combination of mineralogical and micro-analytical data, complemented by a tailored statistical assessment, our study delivers the first systematic evaluation of PGM and BMS assemblages in the LG's of the Bushveld Complex. According to our assessment, no truly unaltered orthomagmatic mineral assemblage is preserved at the site of study – the LG-6 and LG-6A chromite seams exploited at Thaba mine of the northernmost part of the western limb of the Bushveld Complex. Alteration is documented by changes to the PGM, BMS and gangue mineralogy, while chromite remains almost unaffected. Alteration assemblages are similar in both of the two studied LG seams. It was further demonstrated that lateral variation between different drill cores dominates over vertical variation within seam as well as between the LG-6 and LG-6A seams.

A “typical“ PGM spectrum for all Bushveld chromitites as proposed by *e.g.*, Junge et al. (2016) or Oberthür et al. (2016) is not supported by the results of the present study. Even though all included groups of the “typical” PGM were detected, different assemblages of different origin can be distinguished. This study thus extends the assemblages well-documented for the UG-2 (Kinloch 1982; Peyerl 1982; Penberthy and Merkle 1999; Voordouw et al. 2010) to the LG chromitites. Our results may be thus of general applicability, not only for the Thaba mine but also wider parts of the chromitites of the Bushveld Complex, taking the similarities between, *e.g.*, the general mineralogy, mineral chemistry, geology, host rocks within the Bushveld into account.

Acknowledgements

This is a contribution of the German/South African R&D project AMREP—Applied Mineralogy for Resource Efficiency of Platinum-Group Metals—funded by the German Ministry of Education and Research (BMBF; grant number BMBF 033R119E). We thank the Cronimet Mining Group for providing access to their core shed and drill core intersections from the Thaba mine and for the contribution of additional analytical data as well as information on the local geology and beneficiation. Andreas Bartzsch and Roland Würkert are thanked for sample preparation and Dr. Joachim Krause with his help at the EPMA. The comments of Thomas Oberthür to a previous version of this manuscript are gratefully acknowledged.

SC42D	0.24	344.58	344.82	42.9	24.6	3.2	10.8	15.2	0.3	65

Please note that chromitite intersections in bold are considered in detail in this study. Boreholes marked with "D" are deflections of the motherhole and regarded as their most similar sample. Analyses were performed at Set Point Laboratories, Johannesburg. Cr_2O_3, FeO, SiO_2, MgO, Al_2O_3, CaO, P were analyzed by X-ray fluorescence (XRF). "-" = no geochemical analyses are available.

Table 2 Summary of MLA parameters.

SPL parameters		GXMAP parameters	
Voltage (kV)	25	Voltage (kV)	25
Probe current (nA)	10	Probe current (nA)	10
HFW (µm)	750	HFW (µm)	1000
BSE calib.	Au 252	BSE calib.	Au 250
Resolution (pixels)	1000 × 1000	Resolution (pixels)	500 × 500
Pixel size (µm/px)	0.75	Pixel size (µm/px)	2
Quartz EDX-count	2000	Quartz EDX-count	2000
BSE Range	100 - 255	GXMAP trigger	25
Frame Guide Size (px)	30	Step size (px)	8 × 8
Min. grain size (px)	2	Min. grain size (px)	4

SPL = sparse phase liberation measurement mode, HFW = horizontal field width, BSE = back scattered electrons, px = pixel, GXMAP = grain-based X-ray mapping measurement mode, EDX = energy dispersive X-ray spectroscopy

Table 8 Summary of important parameters of determined assemblages for mineral beneficiation.

Assemblage	PGM species	BMS species	Mineral association/ Gangue mineralogy		PGM grain sizes	BMS particle sizes
(I)	PGM-(Cu)-sulfides; alloys of Fe, Sn	Pn + Ccp + Py + Mlr	BMS, Chromite, Silicate		min: <1µm, max: 20µm, avg: 4-5µm	max: 300µm, avg: >30µm
(II)			alteration silicates	silicates		
(III)	PGM-(sulf)arsenides; alloy of Sb, Bi	(Co-rich) Pn ± Ccp ± Py		carbonates, chromite		

Figures

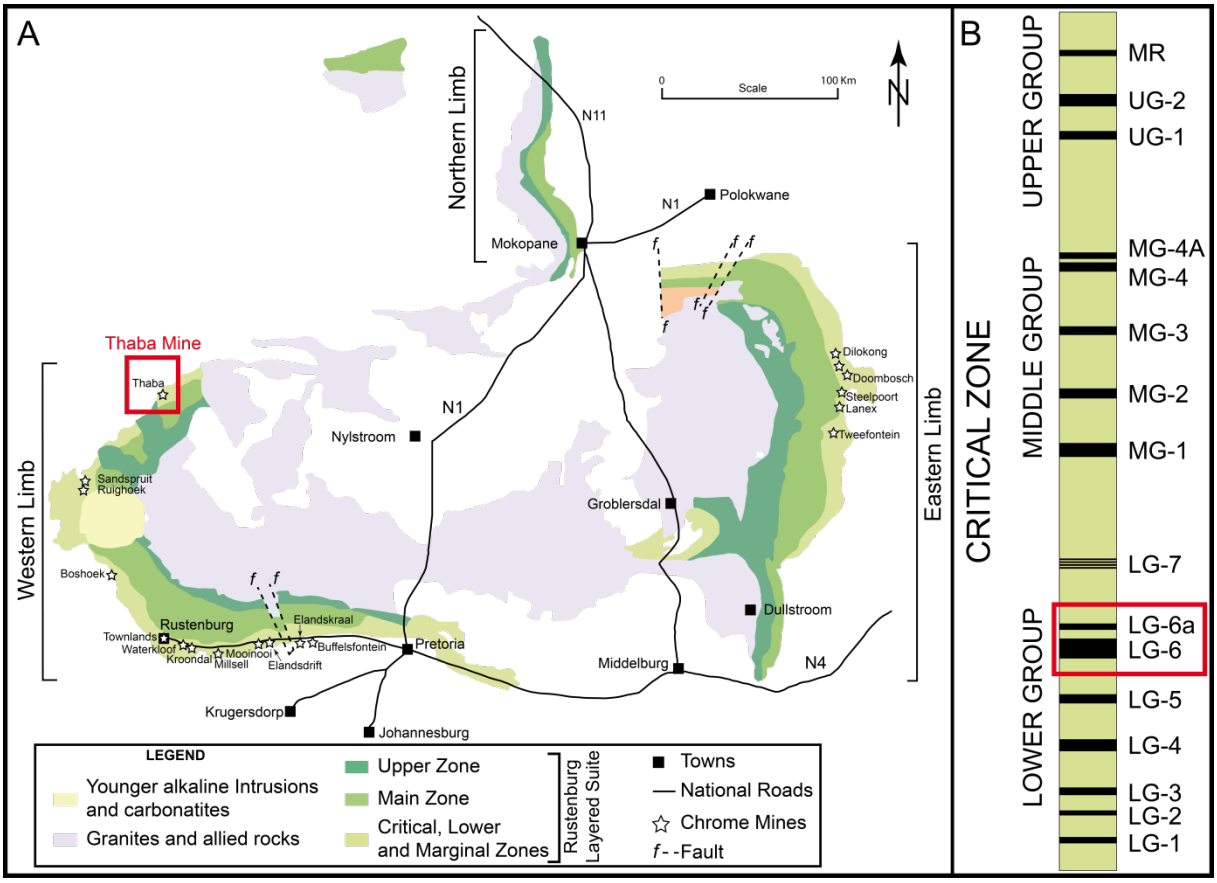

Figure 1(A) Geological map of the Bushveld Complex. The location of the Thaba mine is marked in red. (B) Stratigraphic column of the Critical Zone showing the positions of the major chromitite seams and of the Merensky Reef (MR) (modified from Oberthür et al. 2016).

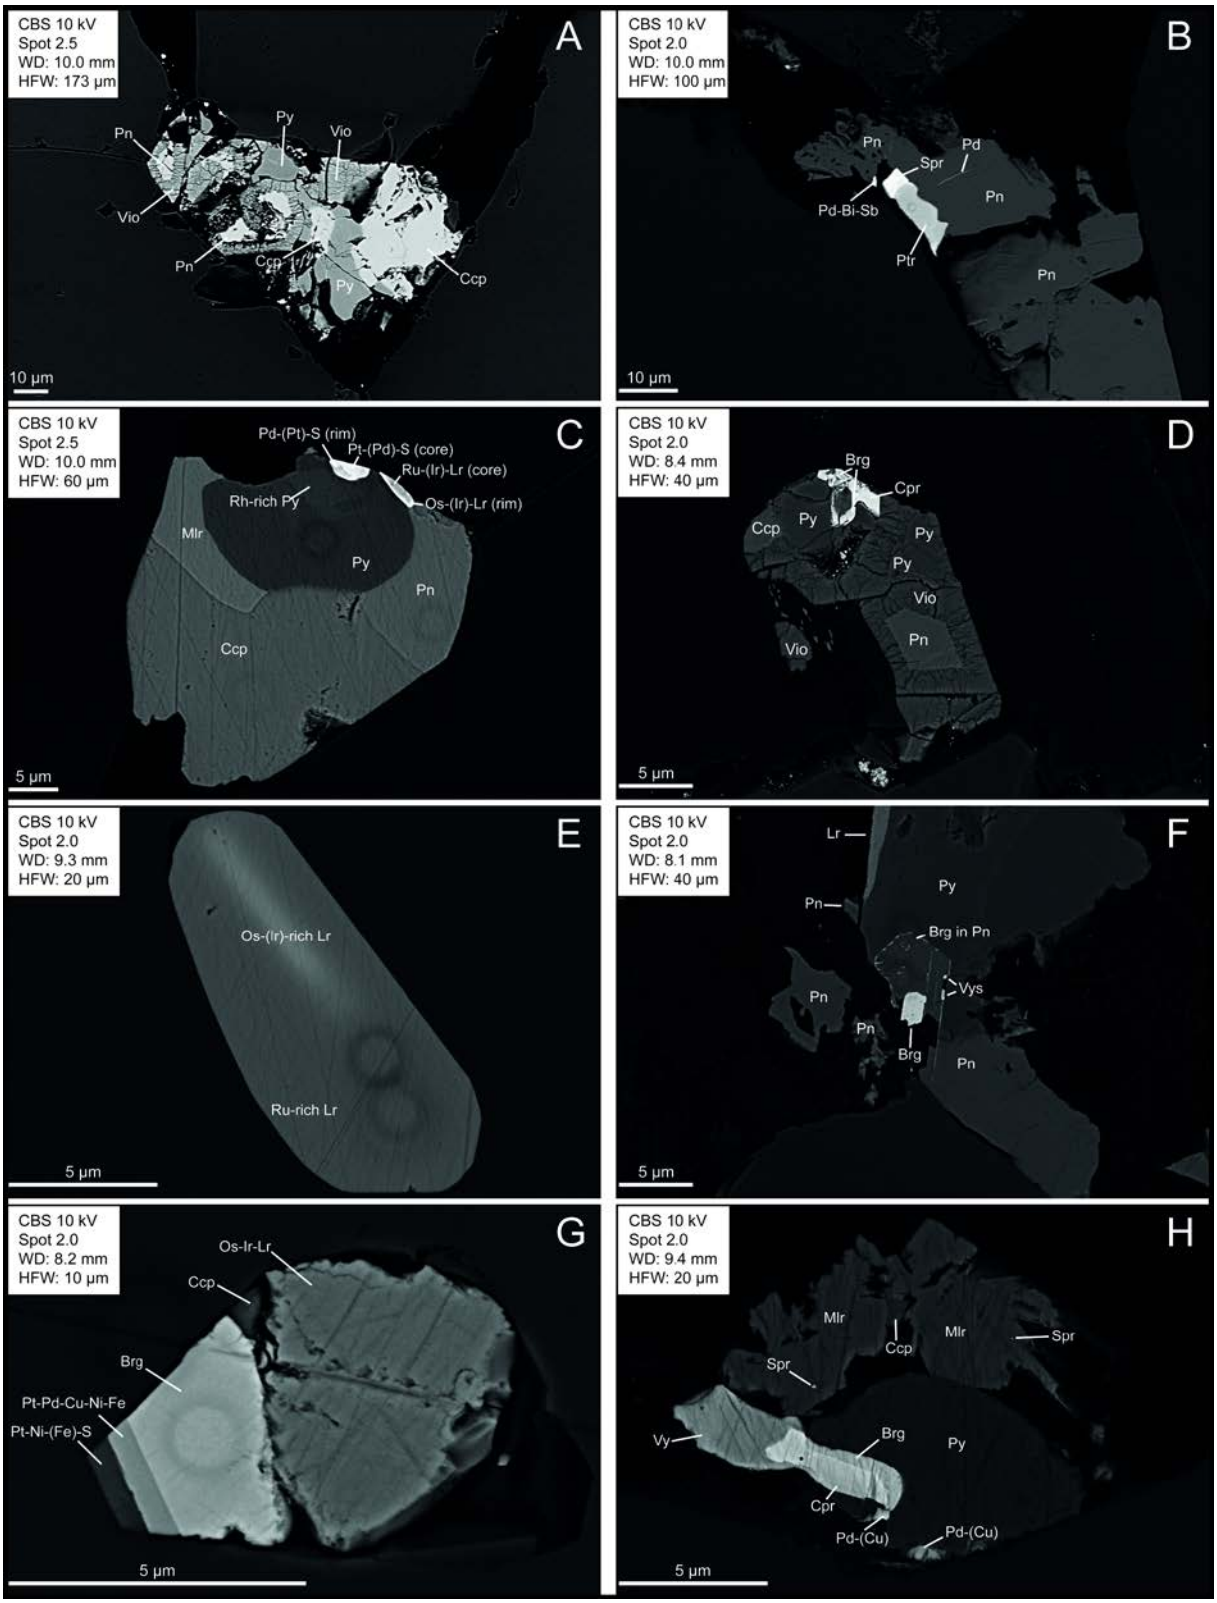

Figure 2 Back-scattered electron (BSE) images of sulfides and PGM in polished sections of the LG-6 and LG-6A chromitite seams. Scale bar and SEM conditions are displayed in the images. (A) Sulfide aggregate containing pyrite (Py), chalcopyrite (Ccp), pentlandite (Pn) and violarite (Vio) in intersection EL28D-LG-6. Please note the alteration of pentlandite into violarite. (B) Platarsite (Plr), Sperrylite (Spr) and a PdBiSb alloy intergrown with Pn in intersection ZK149-LG-6. Please note the Pd dominated lamellae in Pn. (C) Sulfide droplet interstitial to chromite containing millerite (Mlr), Py, Pn and Ccp in intersection SC42-LG-6A. Note the segregation of PPGE and IPGE into different discrete PGM (Braggite (Brg) and Laurite (Lr), respectively) as well as the exsolution of Rh into pyrite (slightly brighter). Both grains show further segregation of Pt and Ru, respectively, located in the core and Pd and Os in the rim. (D) Sulfide aggregate intergrown with a PPGE mineral showing different Braggite

(Brg) – Cooperite (Cpr) compositions in intersection EL28D-LG-6. Note the alteration of Pn into Vio. (E) Laurite grain as an inclusion in chromite in intersection SC42-LG-6A. Note the brighter area due to a higher concentration of Os and Ir. (F) Brg intergrown with sulfides in intersection ZK136D-LG-6A. Note the exsolution of Pt-Pd into the surrounding sulfides during cooling – keeping the original shape of the Brg grain and the formation of Vysotskite (Vys). (G) PGE particle composed of various PGM, both, sulfides (Brg and Lr) as well as alloys as inclusion in chromite in intersection ZK136D-LG-6A. (H) Pt-Pd sulfide of various composition ranging from Vys to Cpr intergrown with various sulfides in intersection SC42-LG-6A. Note the nanoinclusions of Spr in Mlr and a Pd-Cu rich bright phase.

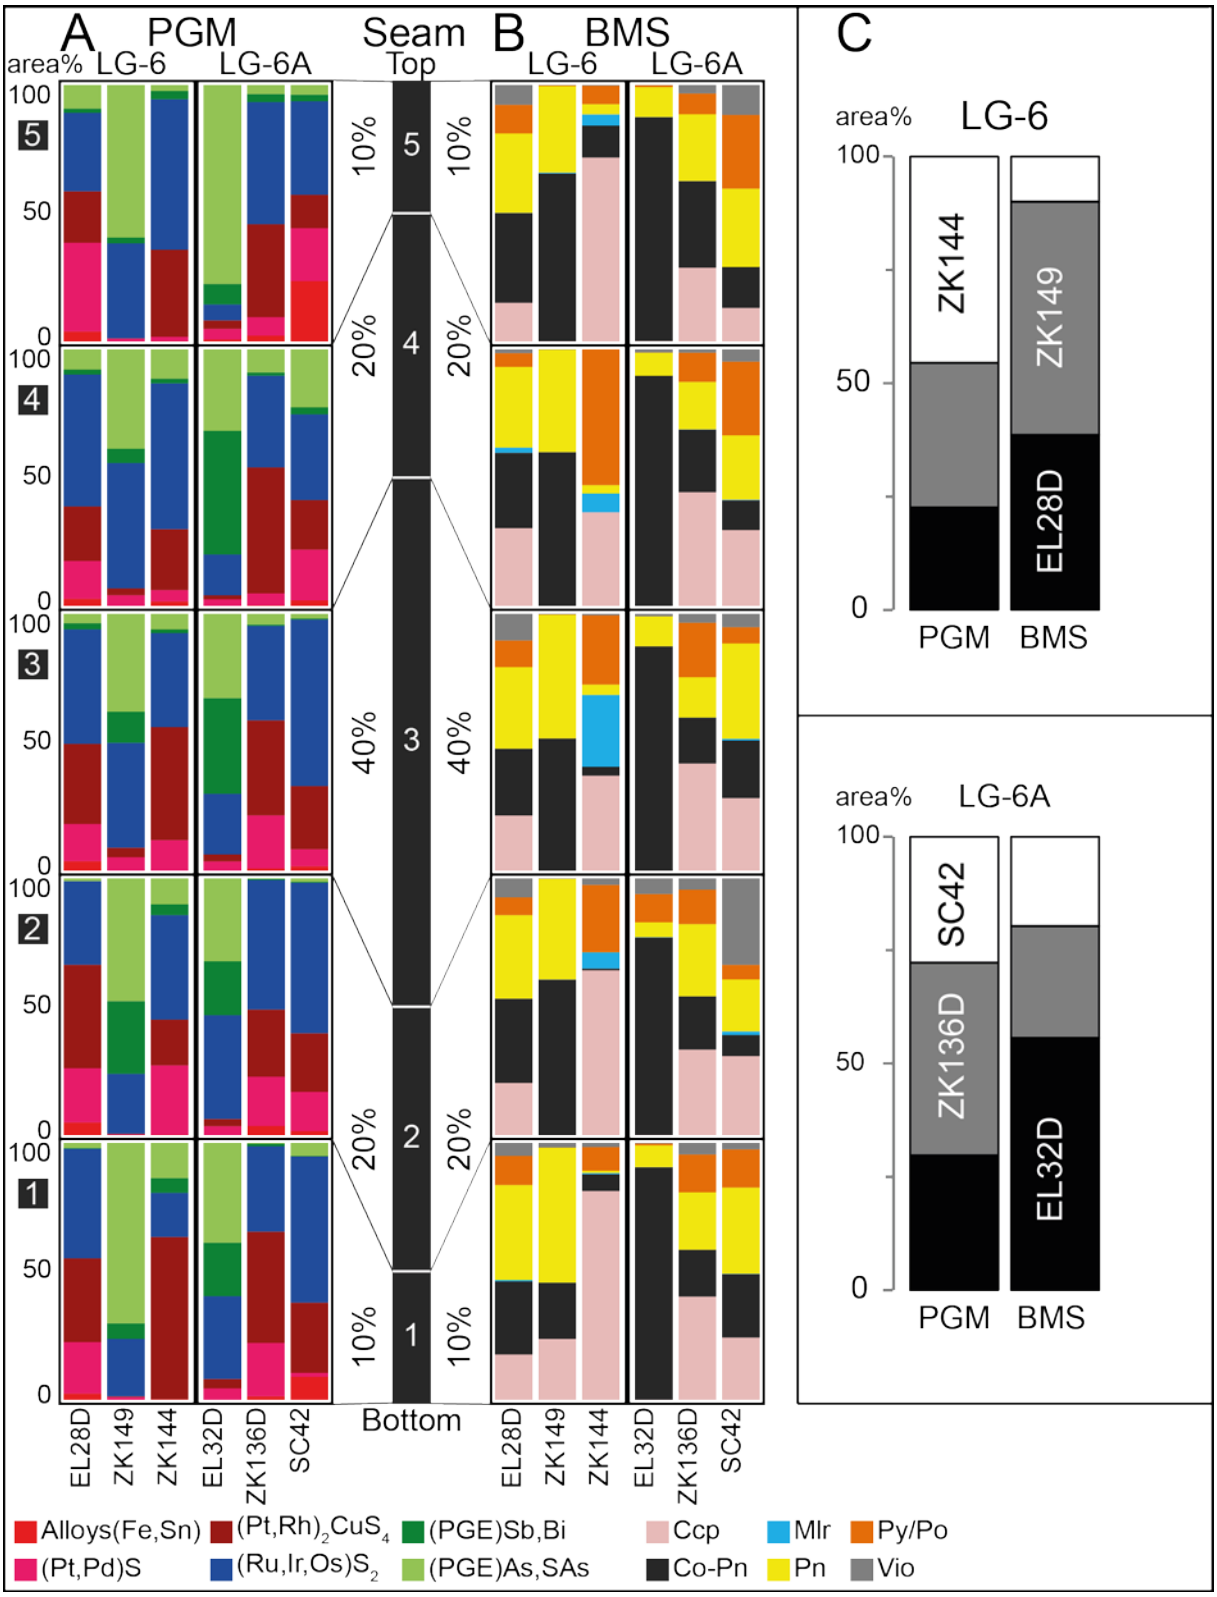

Figure 3 Comparison of MLA thin sections data for drill cores of the LG-6 and LG-6A seam intersections. Thirty samples were analyzed for each seam. (A, B) 100% stacked histograms that show the PGM (for detailed grouping see text) (A) and sulfide (B) assemblages of LG-6 and LG-6A intersections from bottom to top (sectors 1 to 5). (C) Based on normalized thin sections, PGM and BMS area within the sample (µm²) were summed for each drill core separately. The relative distribution of PGM and BMS (area%) in seam LG-6 and LG-6A, respectively, is shown in stacked bar plots. "Seam" displays the division into five sampled distinct sectors (sectors 1-5, from bottom to top) and each sector was sampled randomly to prepare an individual polished thin section for study. For details see text.

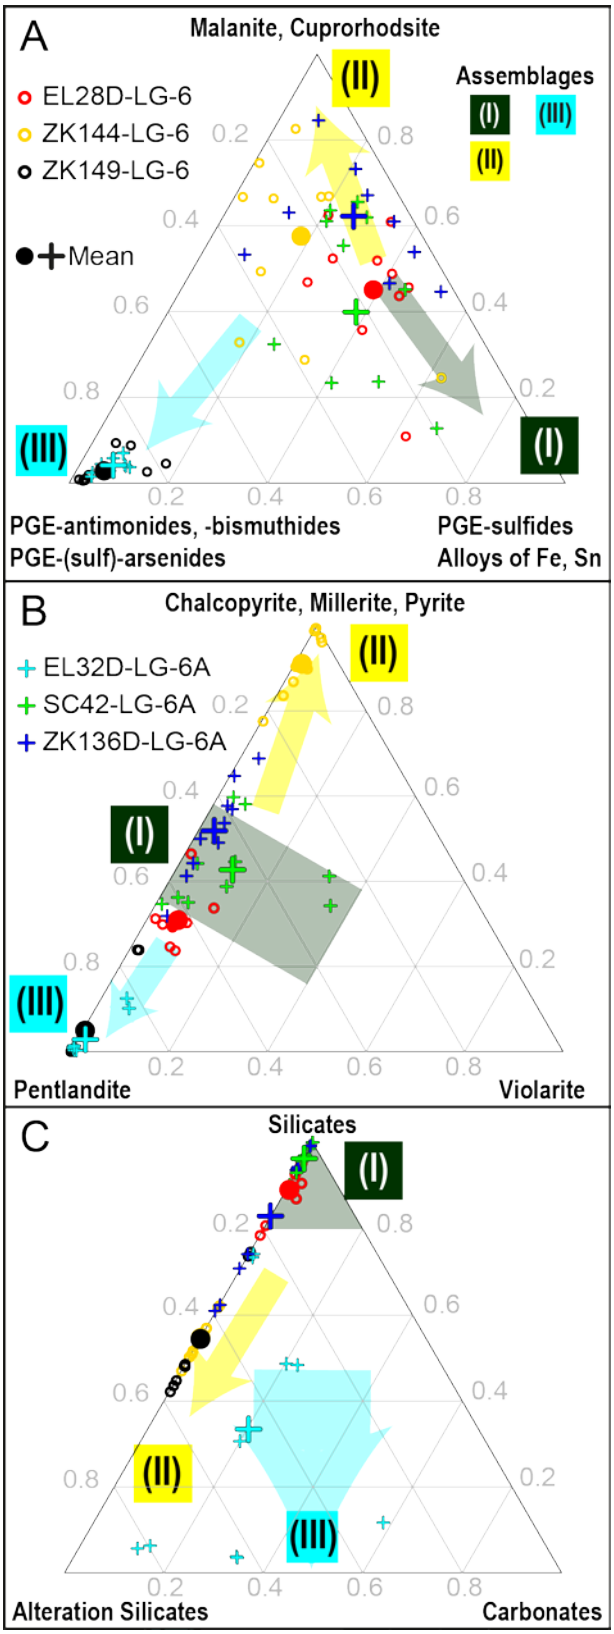

Figure 4 Modal proportions of all thin sections (and the corresponding means) of LG-6 and LG-6A samples for (A) PGM, (B) BMS, and (C) Gangue mineral groups projected in a ternary diagram.

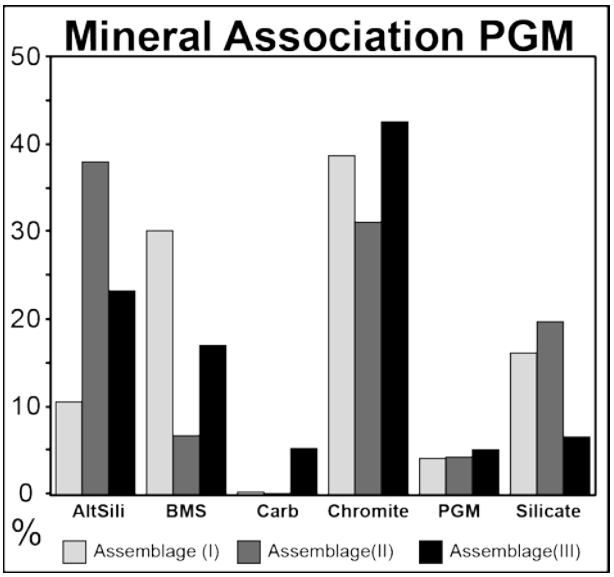

Figure 5 Histogram of mineral association of PGM comparing assemblages (I), (II), (III). Assemblage (I) displays high abundances of PGM-sulfides and alloys of Fe and Sn, while assemblage (II) is dominated by PGM-Cu-sulfides. Assemblage (III), on the other hand, comprises high amounts of PGM-sulfarsenides and PGM-arsenides together with PGE-antimonides, -bismuthides and scant –bismuthotellurides.

Appendix A

Methods – Reproducibility of MLA data

Quantification of the reproducibility and statistical significance of the analyses was performed through (1) analyzing a thin section twice in the same analytical run (in-run duplication), and (2) by re-polishing of the sample to analyze a second surface of the same sample. Results are displayed in Figure A1. In-run analysis displays a relative standard deviation (2σ) for total area%^{PGM} of 5 % for sample ZK149-LG-6 and 4 % for sample ZK136D-LG-6A, while total area%^{BMS} and wt%^{Modal} show 2σ values below 2 % and 0.5 % for both samples, respectively. The combined in-run duplicates of surface A with surface B, 2SDs are 32 % in sample ZK149 and 15 % in sample ZK136D-LG-6A for total area%^{PGM}, while total area%^{BMS} and total area%^{Gangue} show 2σ values below 2 % and 3 % for both samples, respectively.

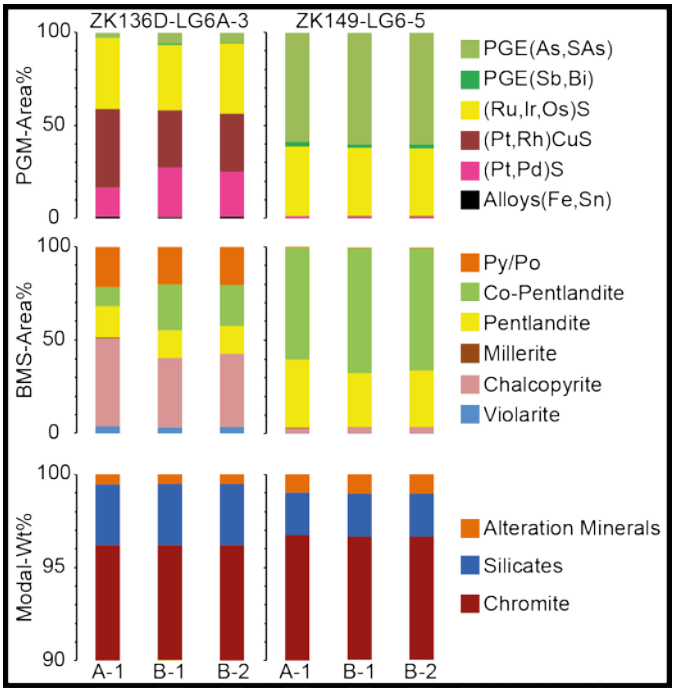

Figure A1 Stacked histograms showing the proportions of PGM species (in terms of area%^{PGM}), base metal sulfides (in terms of area%^{BMS}), and the modal mineralogy in wt% for samples ZK136D-LG-6A-3 and ZK149-LG-6-5. A-1: surface A; B-1: surface B-1; B-2: in-run duplicate of surface B-1.

Methods - Electron probe microanalysis (EPMA)

Quantitative analyses were also performed for amphibole, chromite, clinopyroxene, feldspar, olivine, orthopyroxene, serpentine and talc. Concentrations of Na, Mg, Al (all TAP); Si, K, Ca (all PETJ); Cr, V, Ti (all PETL); Zn, Ni, Co, Fe, Mn (all LIFH) were measured using K_α – lines. Certified reference materials provided by ASTIMEX Standards Ltd. were used for calibration. An electron beam diameter of 5 µm was set at 20kV/ 12 nA and the ZAF approach was used for matrix correction (atomic number–absorption–fluorescence; Philibert, 1963; Reed, 1965; Philibert & Tixier, 1968). Dwell times were set to 15s (Na), 20s (Si, Cr, Ni), and 30s (K, Ca, Fe, Mn), 40s (Mg, Al, V, Ti, Zn, Co). Offline overlap corrections were performed for Zn $L_{\beta1}$ on Na $K_{\alpha1,2}$; Mn $K_{\alpha1}$, Ti $K_{\alpha1}$, Cr $K_{\beta1,3}$ on Al $K_{\alpha1,2}$; Ni $K_{\alpha1}$ on Ca $K_{\alpha1}$; V $K_{\beta1,3}$ on Cr $K_{\alpha1}$; Ti $K_{\beta1,3}$ on V $K_{\alpha1}$; Mn $K_{\beta1,3}$ on Fe $K_{\alpha1}$; and Cr $K_{\beta1,3}$ on Mn $K_{\alpha1}$ as explained in Osbahr et al. (2015).

Finally, EPMA results were used to generate mineral standard spectra with a known composition for MLA measurements. Therefore, mineral standards were taken close to EPMA measurements. This approach allows a detailed differentiation of silicates, such as different feldspar compositions, amphiboles, pyroxenes and alteration silicates.

Results - Geochemistry

5PGE+Au (Pt,Pd,Rh,Ir,Ru,Au) contents are around 1 ppm for LG-6 samples and 1.5 ppm for the LG-6A. In general, the total sulfur content ranges between 100 – 200 ppm (<250 ppm), except intersection ZK144-LG-6, which contains only around 70 ppm. Detailed information are provided with the electronic supplementary material.

Figure A2 displays detailed geochemical assays of two selected drill core intersections of the LG-6 (ZK149-LG-6 and ZK144-LG-6). The profiles display a rather stable Cr_2O_3 content around 43-51 wt%. Slight fluctuations, especially in ZK149-LG-6 display massive chromitite intercalated with ~1 cm pyroxene-rich bands or pyroxene oikocrysts. 5PGE+Au contents are 900 ppb and 950 ppb with a Pt/Pd ratio around 2.2 and 4 and Pt/Ru ratios around 0.9 for intersections ZK144-LG-6 and ZK149-LG-

6, respectively. Both profiles display 5PGE+Au profiles with a “M-shape”; ZK144-LG-6 displays a smooth variation in the overall PGE contents, ranging from ~700 ppb to 1100 ppb, while ZK149-LG-6 displays spikes with minimum single element contents of roughly 370 ppb and a maximum of 1600 ppb. The Ni+Cu plot displays different patterns, however, with variable contents for both of the examples. Cu/ (Cu+Ni) ratios are 0.02 and 0.01 for ZK144-LG-6 and ZK149, respectively. In general, the LG-6 is sulfur poor, with contents ranging from 70 ppm (ZK144-LG-6) to 130 ppm (ZK149-LG-6), on average.

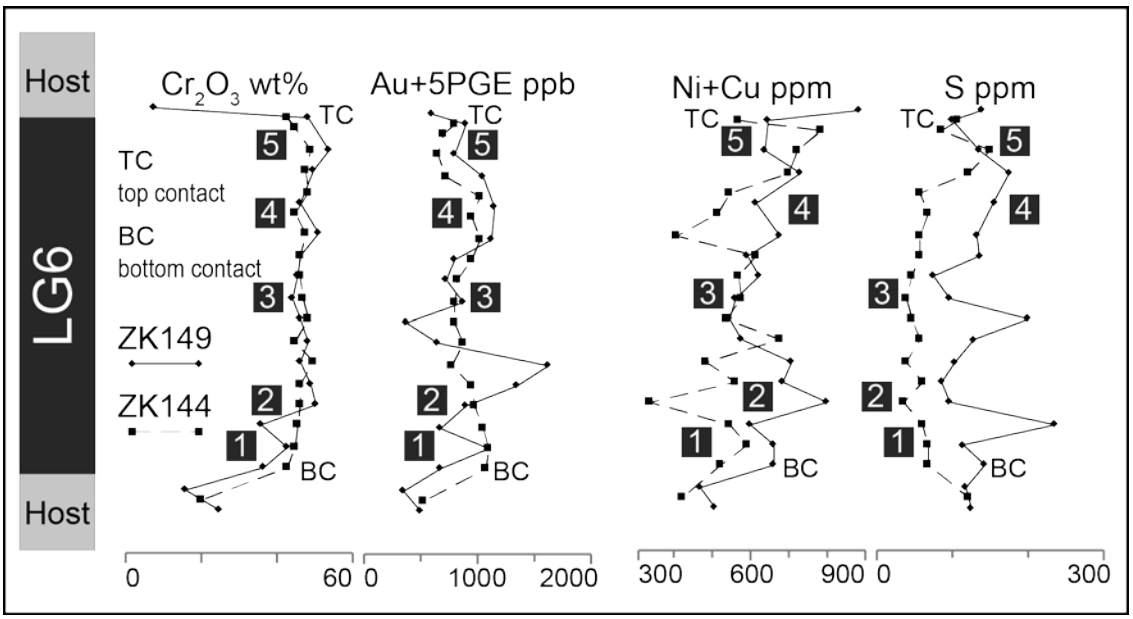

Figure A2 Detailed geochemistry of Cr_2O_3, Au+PGE (6E), Ni+Cu, and S concentrations versus stratigraphic height, normalized to 100 (ZK149: 83 cm; ZK144: 93 cm) in the LG6. Note the bottom (BC) and top contact (TC) of the intersections. 6E analyzed by Ni fire assay, aqua-regia digestion and ICP-MS finish, sulfur analyzed by “LECO” combustion.

Results - EPMA analyses – silicate minerals and chromite

Altogether, 359 analyses on LG-6A samples were obtained to describe the mineral chemistry of various silicate minerals as well as chromite in the LG seams. Table A1displays representative analyses of this sample set, extended by some analyses of important mineral compositions, namely Al-rich chromite, olivine, and serpentine, contained in a MG sample set due to a lack of these minerals in the measured LG sections. Mineral standard spectra for further MLA analysis were taken on grains with a known composition for a better identification during quantitative mineralogical assessment.

Figure A3A displays two different types of pyroxenes. One type yields an orthopyroxene X_{En}=78-85, X_{Fs} = 13-19 and X_{Wo} = 0.5-9 and is hereafter referred to as enstatite. The second type shows a slight trend from augitic to mainly diopsidic compositions and is composed of X_{En}=45-52, X_{Fs} = 5-9 and X_{Wo} = 38-48 (hereafter referred to as diopside). Amphiboles can be best described as magnesio-hornblende. Feldspars shown in Figure A3B yield plagioclase compositions ranging from andesine to bytownite, however, also minor albite and anorthite were analyzed by EDX measurement. Furthermore, sanidine with X_{Or} up to 90 % was encountered. For both, pyroxene and feldspar, there were no significant differences between samples detected. Chromite was analyzed in sample EL32D_LG-6A and ZK136D_LG-6A (Figure A3C). Data might indicate differences between samples, as sample EL32D_LG-6A displays low Fe^{3+} and slightly higher Al contents than ZK136D_LG-6A.

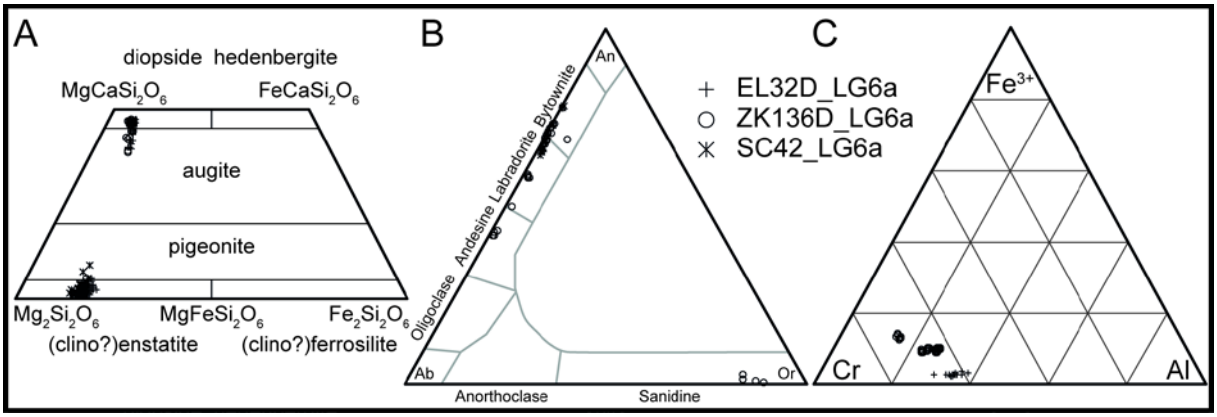

Figure A3 Ternary plots of EPMA measurements. (A) Classification diagram of pyroxene after Morimoto (1988). Both types of pyroxene – enstatite (orthopyroxene) and (augite)-diopside are rather chemically homogeneous. (B) Classification diagram of feldspar with endmembers anorthite (*An*), albite (*Ab*), alkalifeldspar/ orthoclase (*Or*). Beside plagioclase with variable composition alkali feldspar with sanidine composition was detected. (C) Ternary plot of trivalent cations, Cr, Al and Fe^{3+} in chromite. Note that the data show only little variation, however, all analyses of intersection EL32D_LG-6A display a lower concentration in Fe^{3+} compensated by a higher Al content.

Table A1 Representative EPMA analyses of all relevant silicate minerals and chromite, used for the MLA Mineral Reference List.

Please note the analyses for Al-chromite, olivine, biotite and serpentine were taken from a different sample set of MG1 samples from the same locality. Calculation of chromite is normalized to 32 O; pyroxene is normalized to 6 O; olivine is normalized to 4 O; feldspar is normalized to 8 O; mica is normalized to 11 O; amphibole is normalized to 23 O; talc is normalized to 22 O; and serpentine is normalized to 14 O. apfu – atoms per formula unit.

ANOVA

An ANOVA was performed – followed by standard F-tests – to investigate the variability of the samples and to determine assemblages for classification according to the sub-compositions area%^{PGM}, area%^{BMS} and area%^{Gangue} (see legend in Figure A4A). Variability of the samples was tested for four explanatory factors ("surfaces A/B", "intra seam", "inter core" and "inter seam" (see in the methods section for definition of these explanatory factors). "Surfaces A/B" compares the results obtained for the two different polished surfaces (A and B) analysed for each sample. This explanatory factor is found to have no significant influence on the tested ANOVA model, which allows the conclusion that the exact position of the sample surface examined by MLA has no significant effect on the results obtained. Most notably, it suggests that the "nugget effect" (small scale variability) is negligible.

The explanatory factor "intra seam" considers the variance between samples of a different stratigraphic position within a sampled seam, *i.e.* if seams have systematically different mineral assemblages within their respective confines. The factor "intra seam" does have a significant influence for the variance of both, area%^{PGM} and area%^{BMS} and a highly significant influence for the variance of area%^{Gangue}. The two factors "inter seam" (considering systematic differences between the two studied seams, LG-6 and LG-6A) and "inter core" (considering systematic differences between different drill core intersections) show close interrelation, meaning that variance induced by "inter seam" will be a part of the variance induced by "inter core". While the F-tests for the factor "inter seam" are non-significant for area%^{PGM} and area%^{BMS}, and highly significant for area%^{Gangue}, the factor "inter core" yields highly significant results in all cases. This suggests that systematic differences between distinct seams intersected within the same drill core are of minor importance compared to differences encountered between drill cores from different sites on the mine lease area.

159 Figure 4A shows the variance distribution for the two most relevant factors. “Inter core” is by far the
160 most important explanatory factor, explaining between 59 and 77 % of the total variance. In
161 comparison, the factor “intra core” explains only 6 % of total variance – a value that is similar for all
162 sub-compositions. As mentioned above, the factor “seam” was not considered further, as it explains
163 only between 2 and 13 % of the “inter core” variance for area%^{PGM} and area%^{BMS} and area%^{Gangue}. The
164 factor “residuals” reports the variance that cannot be assigned to any of the previously mentioned
165 factors and ranges between 23 and 35 % of the total variance. A detailed evaluation of the
166 explanatory factor “inter core” for all sub-compositions based on ratios of certain mineral groups is
167 shown in Figure A4B. The chosen ratios explain the bulk total variance, *i.e.* reflect the distribution of
168 the group members. According to the ANOVA model the main part of the total variance in area%^{PGM}
169 is invested in predicting the ratios [PGE -sulfarsenides and PGE-antimonides, -bismuthides vs. PGE –
170 sulfides, -Cu-sulfides and -alloys of Fe,Sn]; *i.e.* these groups show a strong negative correlation and
171 form distinctly different mineral assemblages. Furthermore, the ratio [PGE-Cu-sulfides vs. PGE –
172 sulfides and –alloys of Fe,Sn] explains a significant portion of the total variance, and may be used to
173 distinguish two more PGM mineral assemblages. The variability of IPGE -sulfides is rather low and
174 only marginally explained by the factor “inter core”. The area%^{BMS} “inter core” variance is mostly
175 related to the variability of (Co-rich) pentlandite with respect to the geometric average of the other
176 four BMS considered (chalcopyrite, millerite, pyrite and violarite). The ratios [chalcopyrite vs.
177 millerite] and [chalcopyrite and millerite vs. violarite] do also have relevant contributions. The
178 mentioned relationships correspond well to the area%^{PGM} distribution, *i.e.* PGE-sulfarsenide/ -alloy of
179 Sb,Bi-rich assemblages represent the same set of samples as the (Co-rich) pentlandite dominated
180 BMS assemblages (forming assemblage (III)). On the other hand, PGE-(Cu)–sulfides and -alloys of
181 Fe,Sn occur together with rather chalcopyrite, millerite, pyrite, violarite dominated samples –
182 resulting in assemblage (I) and (II). The latter assemblages can be further subdivided into PGE-Cu-
183 sulfides + chalcopyrite and millerite-rich samples (assemblage (II)), in contrast to assemblage (I)

where a PGE-sulfide-rich assemblage is associated with a rather variable BMS assemblage consisting of chalcopyrite, pentlandite, pyrite and variable amounts of violarite.

In the area%^{Gangue} sub-composition total "inter core" variance is best described using the ratios [alteration silicates and silicates vs. carbonate] followed by [alteration silicates vs. silicates]. While carbonate-rich samples are associated with PGM-BMS assemblage (III), silicate-rich samples dominate PGM-BMS assemblage (I). Significant amounts of alteration silicates may occur in samples belonging to PGM-BMS assemblages (II) and (III).

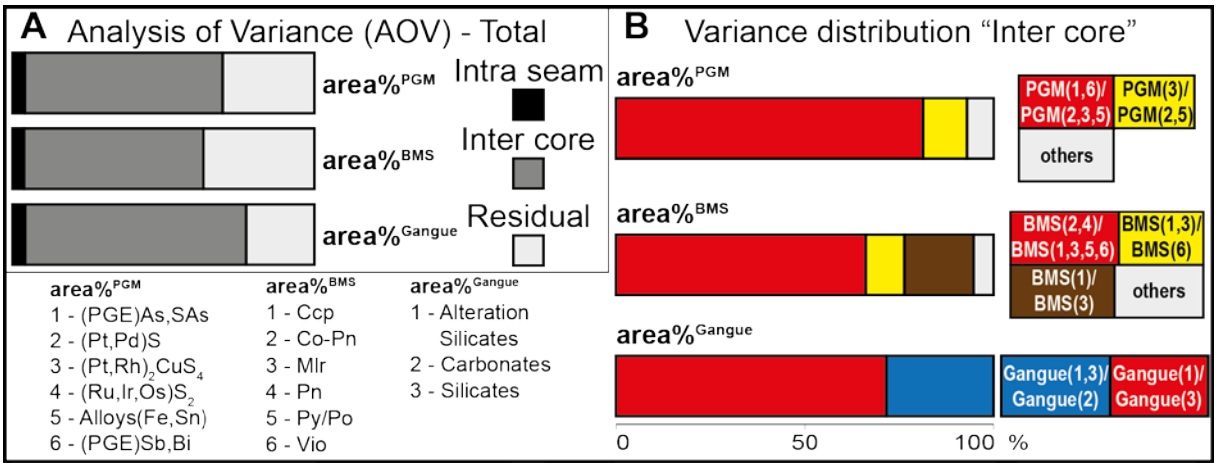

Figure A4 Stacked histograms of the results of an analysis of variance (AOV) of the modal mineralogy for PGM, BMS and rock forming minerals (Others). (A) Total variance distribution for area%^{PGM}, area%^{BMS} and area%^{Gangue}. (B) Variance distribution based on defined ratios of certain PGM/BMS/Gangue groups. For simplification, further reference to any group members will be as following, e.g. (PGE)As,AsS = PGM(1); Alloys(Sb,Bi) = PGM(6); Ccp = BMS(1), etc. (cf. Table 6; legend in (A)).

Cluster analysis

For a quantitative assessment of the variability of the mineral association a cluster analysis was performed according to the sub-compositions of PGM (without IPGE sulfides) and BMS. The results were linked to the mineral assemblages defined in the previous chapter (*ANOVA*).

Despite the very low total abundance of BMS (< 0.02 area% in all samples), PGM show a strong preferred association with BMS; they also show a close association with alteration silicates, occurring both in interstitial positions and as inclusion. PGM are only to a much lesser extent associated with

206 silicates and chromite. PGM occur predominantly interstitial to chromite (with minor inclusions cf.
207 Figure 2G). BMS show a very similar association to PGM.

208 The cluster analysis results in three distinct clusters: a dominant and two minor, for both PGM
209 [$n_{Cluster1}$ = 5, $n_{Cluster2}$ = 16, $n_{Cluster3}$ = 39] and for BMS [$n_{Cluster1}$ = 39, $n_{Cluster2}$ = 12, $n_{Cluster3}$ = 9] (Figure A5).
210 PGM cluster 1 consists of samples with a high silicate and lower chromite content, where most PGM
211 occur in association with BMS. Cluster 2 includes carbonate-rich samples and PGM associated with
212 alteration silicates and carbonates. Cluster 3, on the other hand, represents high chromite, high
213 alteration silicate and low silicate content samples; PGM in this cluster are intergrown with alteration
214 silicates and silicates. BMS cluster 1 is marked by high silicate/ alteration silicate ratios, where BMS
215 occur predominantly as polymineralic aggregates intergrown with both alteration silicates and
216 silicates. In contrast, the BMS cluster 3 lacks BMS aggregates and and includes samples with low
217 silicate/alteration silicate ratios. BMS are closely associated with silicates and alteration silicates in
218 these samples. Similar to PGM cluster 2, the BMS cluster 2 represents carbonate-rich samples. Both,
219 PGM and BMS mineral associations thus define similar clusters - implying a separation of silicate-
220 dominated from alteration silicate and/or carbonate-dominated clusters. BMS and PGM tend to be
221 associated with alteration minerals, if present, hence, establishing cluster 1 as typical for assemblage
222 (I) seems valid. Furthermore, cluster 2 can be assigned to assemblage (III), while cluster 3 mainly
223 represents the alteration silicate-rich members of assemblage (II) and (III).

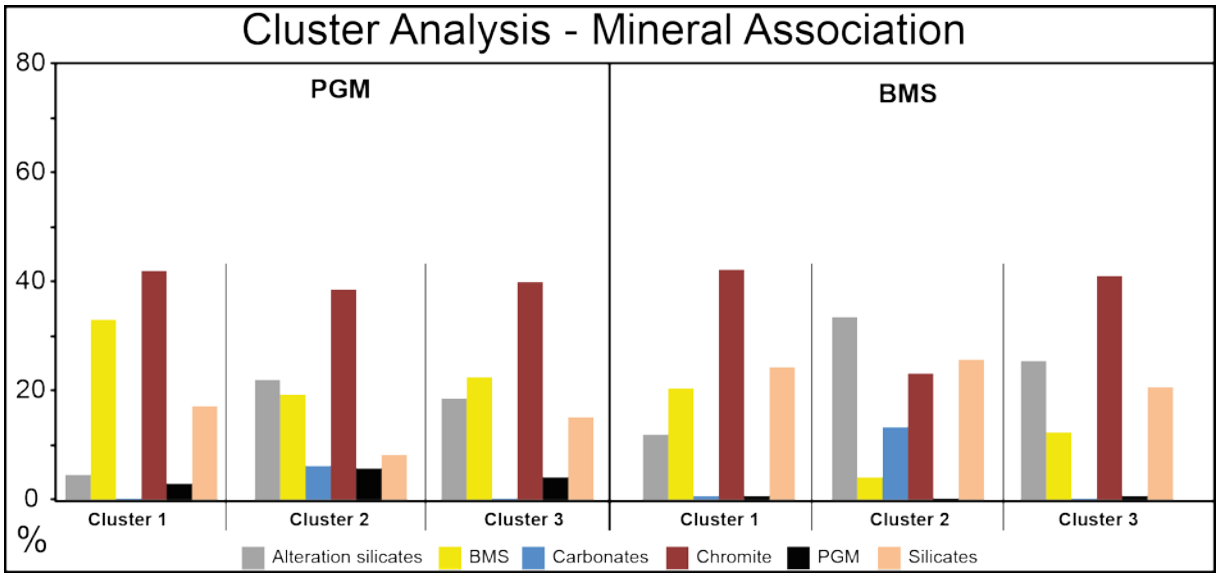

Figure A5 Histograms of average mineral associations of clusters defined by two cluster analysis for sub-compositions PGM (without IPGE –sulfides) and BMS, respectively. Color codes are explained below corresponding histograms. Cluster (I) displays high abundances of PGM-sulfides and alloys of Fe and Sn together with BMS dominated by pentlandite + chalcopyrite + pyrite. Cluster (II) comprises high amounts of PGM-sulfarsenides and PGM-arsenides together with PGE-antimonides, -bismuthides and scant –bismuthotellurides. Corresponding BMS are strongly dominated by pentlandite and Co-rich pentlandite. On the one hand, cluster (III) represents samples dominated by PGM-Cu-sulfide corresponding with high amounts of chalcopyrite. On the other hand, a minor amount of samples contains significant portions of PGM-sulfarsenides, -arsenides, -antimonides, and -bismuthides corresponding with a high abundance of pentlandite.
